Still, there are clear signs that the container shipping industry is (slowly) walking a different path. For example, Maersk Line, one of the companies that have always embodied the race for market shares and big ships is no longer pushing for bigger vessels and wants to focus on profits through a stronger focus on service quality and integrated logistics services supported by data. Also other shipping lines are developing a much stronger supply chain focus and embrace digitalization. The increased digitalization of the container market through platforms and apps will create a far greater transparency in terms of freight rates, vessel positions and port capacities, and will facilitate demand forecasting exercises. Data analytics will give customers and other actors in the supply chains much more possibilities to compare, benchmark, and play-off one shipping line against the other. These developments challenge shipping companies to become an integral part of these digital transformation processes by making their own processes open to standardization and transparency (instead of being subject to what other players impose) and to extract new business models and revenue streams from the digital environment. These transformation processes within container shipping lines are not easy, as the weak financial base of most companies does not leave a lot of room for large-scale investment programs in initiatives with a long or highly uncertain payback period.

The same applies to the enormous pressure on container lines to prepare for zero emission vessels in the foreseeable future. At present, container ships carry about 80% of global trade and contribute about 3% of the world's emissions. The IMO has developed regulations on energy efficiency to support the demand for ever greener and cleaner shipping (Cariou et al., 2019). Since 1 January 2020, the limit for sulfur in fuel oil used on board ships operating outside designated emission control areas (ECAs) is 0.5% m/m (mass by mass). There is an even stricter limit of 0.1% m/m in effect in ECAs, which have been established by the IMO. Shipping lines had to take action by implementing a range of measures, including the switch to other low-sulfur fuels (e.g., LNG, low-sulfur Marine Diesel Oil, or biofuels), by retrofitting vessels with so-called scrubbers designed to remove sulfur oxides from the ship's engine and

boiler exhaust gases, by reducing vessel speed (i.e., slow steaming), by designing fuel-efficient and low-emissions vessels, etc. The longer-term challenges are far greater with a push for zero-emission ships by 2050. It is hopeful to observe that, despite the current market conditions and poor margins, some of the world's largest container shipping companies are pledging to cut net carbon emissions to zero by 2050. This will only be feasible if the entire chain from engine makers and shipbuilders to new technology providers come up with carbon-free ships by as early as 2030 and if the final customers share the cost burden to invest in new technologies related to biofuels, hydrogen, electricity or even wind or solar power. Shipping companies are aware that not just governments and countries, but also companies and industries need to make a change.

Biography

Theo Notteboom is Professor in Port and Maritime Economics and Management. He is Director and Research Professor at Centre for Eurasian Maritime and Inland Logistics (CEMIL) of China Institute of FTZ Supply Chain of Shanghai Maritime University in China. He is Chair Professor "North Sea Port" at the Maritime Institute of Ghent University. He also is part-time Professor at University of Antwerp and the Antwerp Maritime Academy in Belgium. He is cofounder and codirector of www.porteconomics.eu, an online platform on port studies. He is past President (2010–2014) and Council Member of International Association of Maritime Economists (IAME). He is Editor, Associate Editor, or Editorial Board Member of a dozen leading academic journals in the area of maritime economics and logistics. His work is widely cited.

Introduction to the Shipping Industry

The Main Economic Participants

More than 90% of world trade is carried by sea. Vessels are required for this purpose, for offering the sea freight transportation service to those lacking it. Thus the shipping industry provides a service, not a product; that is, the transportation of commodities (or people) from point A to B in the world. This service is measured in ton-miles, that is, the quantity of tonnage transported times the distance.

A large number of economic participants, maritime stakeholders, are involved in the sea transportation service, and they collectively constitute the maritime industry. They include shipowners, charterers, ship managers, freight forwarders, cargo owners, brokers, classification societies, seafarers, ports, shipyards, bunker suppliers, scrapyards, repair and maintenance yards, equipment manufacturers, marine insurers, maritime flag states, regulators, lawyers specializing in maritime law, financiers providing capital for the needs of the industry, and others.

The degree of integration between the functions of economic participants differs between the various shipping sectors, which are presented in section, *The Main Sectors of the Shipping Industry*. Shipping companies' economic activities are structured into entities, with their legal nature ranging from single purpose companies (or single purpose vehicles, SPVs)—owning a single vessel, to family businesses—owning a number of ships, to fully integrated shipping divisions or large corporate structures, which may be private or listed in one of the major stock exchanges around the world. Their economic activity is subject to the various shipping markets—the freight, the newbuilding, the sales and purchase, the demolition markets, the bunker, the money and capital, and the risk management markets, amongst others.

The Main Sectors of the Shipping Industry

Merchant shipping refers to the transportation of commodities, which are carried as bulk, break-bulk/general or containerized cargoes.

Bulk shipping involves large volumes of homogeneous commodities transported around the world in bulk, mainly on a “one ship, one cargo” basis. The cargo transported can be dry or liquid. Bulk carriers are used for the transportation of dry commodities in bulk, and tankers for the transportation of liquid ones, while combined carriers can carry either dry or liquid cargoes. There are also

specialist vessels, particularly designed to accommodate the transportation of commodities with special handling or storage requirements, such as the transportation of gas under pressure, refrigerated products, etc.

There are also cargoes which do not justify the use of the whole ship because of their consignment size. These are called “general cargoes” and include machinery, heavy cargoes, sling cargoes, pallets, drums, etc. Two broad groups are distinguished: (1) conventional or break-bulk cargoes, involving transportation of individual items (e.g., pieces of machinery, bags, cases, bales, drums, barrels, etc.; and (2) unitized cargoes, which involve containers, pallets, slings (e.g., planks of wood lashed together), etc. Multipurpose and specialized vessels, as well as containerships, are used for the transportation of these cargoes. Thus containerships carry intermodal containers, which are shipping containers of standardized dimensions that can be carried across different modes of transport (rail, truck, and ship) and handled via automated transport system technologies. Cargoes that are unitized or impossible/ineffective to be transported in bulk are carried in intermodal containers.

Thus the decision of what type of vessel will be used for the transportation of a commodity depends (among other factors) on the particular characteristics of the commodity, as well as its consignment size. For any commodity, there are typical parcel (consignment) sizes for transportation, which appear over a range—the so called “Parcel Size Distribution.” This range is determined by the economics of the industry demanding the commodity as well as its physical and economic characteristics^a.

The different commodities and vessels used for their transportation define the different sectors of merchant shipping, which can be summarized as follows:

- The dry bulk sector, which involves bulk carriers for the transportation of dry cargo in bulk form, such as iron ore, coal, grains, bauxite and alumina, and other minor bulk commodities.
- The sector of general cargo vessels, which carry other dry cargo that is not shipped in bulk or in not large enough sizes to justify the use of bulk cargo transportation.
- The oil and product tanker sectors, where crude oil and oil product tankers are used for the transportation of crude oil and refined products.
- The container sector, which involves the transportation of finished products, such as manufactured commodities, electronic goods etc. in containerships.
- The offshore sector, with vessels involved in the supply of oil extracting platforms.
- Several other types of vessels serve the different sectors of merchant shipping, like combined carriers, specialized vessels, tugs, crew/workboat fleet, etc.

As at the start of July 2019, the world fleet comprised 97,142 vessels with a total carrying capacity of 2,020.71 million deadweight (DWT)^{b,c}. As can be observed in **Fig. 1**, bulk carriers constituted the largest part of this and amounted to 43% of the world total carrying capacity (857.78 million dwt, with 11,643 vessels), tankers comprised the second biggest component of the world fleet with 30% share (609.83 million dwt, 6,873 vessels) while containerships came third with a 13% share (269.92 million dwt, 5,311 vessels). LNG (Liquefied Natural Gas) and LPG (Liquefied Petroleum Gas) carriers amounted to 3% of the world total fleet, while other types of vessels—like combined carriers, offshore vessels, anchor handling tugs, cruise ships, crew/workboat fleet, etc.—comprised 11% of the world total carrying capacity.

Fig. 2 shows the development of the world fleet in terms of DWT capacity for the years 1970–2018. The increase in carrying capacity, from 57.7 to 817.5 million DWT for bulk carriers, and from 138.8 to 582 million DWT for tankers, is impressive, and is a consequence of the globalization process in production and services and the consequent need for sea-transportation to serve its needs. This continuously growing need for transportation of raw industrial materials and fuels over time includes commodities such as iron ore, coal, crude oil, and its products, which are indispensable in industrial production. As observed, the world total carrying capacity has more than doubled from 2005 (921.7 million dwt) to 2019 (1976.5 million dwt), with carrying capacity increasing in all segments.

Up to 2003, tankers had the greatest share in the world fleet, followed by bulk carriers. This has been reversed since 2004, partially due to switches from long-haul to short-haul routes in the transportation of oil, which led to a decrease in the average tanker size (see section *Sector Segmentation Per Vessel Size*), but also due to the over-ordering of dry bulk vessels during the booming years of 2003–07.

Sector Segmentation Per Vessel Size

The shipping industry aims to provide fast and cheap transportation service around the globe. In comparison to all alternative modes of cargo transportation, particularly over large consignments and/or longer distances, waterborne transportation is the most economical mode on a per-unit of cargo basis. For bulk vessels, the unit cost of transporting a ton of cargo is calculated as the sum of the capital, operating and voyage expenses, divided by the tonnage the ship can carry. Since capital, operating and voyage costs do not increase proportionally with tonnage capacity, the unit cost generally falls as the size of the ship increases. In real terms,

^a For instance, iron ore is transported in large parcels of around 180,000 tons, as the steel industry which is using it as a raw material requires such large consignments, in order to make it cheaper for them to be transported. Also, it does not require special storage facilities—open land next to the steel mill is sufficient for storage as weather does not affect it, while the commodity can be handled in bulk. As a consequence, it will be transported on a one ship one cargo basis in relatively large consignments, as this will reduce the unit (per ton) transportation cost. PSD's vary over time as the world economy, trade patterns, technological developments in shipping and commodity economics change.

^b Source: Clarksons SIN (Shipping Intelligence Network).

^c Deadweight is a measure of the carrying capacity of a vessel, calculated as the sum of the weights of cargo, fuel, fresh water, stores, and crew that it can carry.

Figure 1 World fleet per sector (July 2019, measured in million dwt and as percentage of total world fleet). *Source: Figure created by the authors. Data derived from Clarksons SIN.*

Figure 2 World fleet development (in million DWT, 1970–2018). Note: For the years 1970–95, Tanker and Bulk Carrier fleets only are reported due to data unavailability for the rest of the sectors. Similarly, for all subsequent years, data are depicted depending on its availability. *Source: Figure created by the authors. Data derived from Clarksons SIN.*

the cost per ton of transportation has been reducing continuously since the Second World War, due to increases in the size of the vessels carrying the cargoes and thus economies of scale setting in. As shown in Fig. 3, from January 1970 to January 2019, the average bulk carrier increased in size from 28,095 dwt to 73,427 dwt.

However, since demand for transportation is measured in ton-miles, there may be cases where changes in trading routes (for example from long-haul to short-haul ones) may result in a decrease in vessel sizes. As can be seen in Fig. 3, even though the average tanker vessel doubled in size from January 1970 to January 2019, with the greatest increase observed during the 1970s (from 43,714 dwt in January 1970, to 100,434 dwt in January 1980), thereafter there has been a decrease due to switches from long-haul to short-haul routes in the transportation of oil.

Figure 3 Development of the average bulkcarrier and tanker sizes overtime (1970–2019, in thousand dwt). *Source: Figure created by the authors. Data derived from Clarksons SIN.*

Table 1 Dry bulk sector segmentation per vessel deadweight capacity.

Segment/Vessel type	Vessel DWT capacity
Very Large Ore/Bulk Carrier (VLOC/VLBC)	200,000–400,000 dwt
Valemax ^a	400,000 dwt
Capesize	120,000–200,000 dwt
Newcastlemax ^b	Approx. 185,000 dwt
New Panamax	100,000–120,000 dwt
Panamax	65,000–100,000 dwt
Kamsarmax ^c	Approx. 82,000 dwt
Supramax	50,000–61,000 dwt
Handymax	40,000–65,000 dwt
Handysize	10,000–40,000 dwt

^aSubcategory named according to the cargo owner/vessel charterer: Valemax vessels comprise a fleet of very large ore carriers -VLOC-owned or chartered by the Brazilian mining company Vale S.A. to carry iron ore from Brazil to European and Asian ports.

^bSubcategory named according to infrastructural particularity: Newcastlemax is the largest vessel able to enter the port of Newcastle in Australia.

^cSubcategory named according to infrastructural particularity: Kamsarmax got its name by meeting the 229-meter limit on ship length at the Port of Kamsar, a major bauxite shipping port in the Republic of Guinea on the west coast of Africa.

Source: Created by the authors using various sources.

Another feature of water transportation economics and particularly those of bulk shipping freight markets is that shipping freight rates represent a small proportion of the final value of the transported product. As a consequence, a large change in freight rates will not result in a substantial move in the price of the commodity being transported, and as a result on the final demand for the commodity, rendering demand for sea transportation inelastic.

The dry bulk shipping sector comprises the vessel categories per deadweight capacity presented in Table 1.

An important differentiation between vessel sizes involves the availability of cargo-handling equipment on the vessel. Typically, vessels below Panamax size are geared, and thus are self-sufficient in terms of being able to approach even ports of the world with less developed cargo-handling facilities.

In the tanker sector, one can distinguish between the following on the basis of the type of cargo they carry:

- crude oil or dirty tanker carriers,
- crude oil-product or clean tanker carriers, and
- gas carriers.

Table 2 Tanker sector segmentation per vessel deadweight capacity.

	Segment/Vessel type	Vessel DWT capacity	
Crude oil	Ultra large crude carrier (ULCC)	> 320,000 dwt	
	Very large crude carrier (VLCC)	200,000–300,000 dwt	
	Suezmax	115,000–200,000 dwt	
	Aframax	70,000–115,000 dwt	
	Panamax	50,000–70,000 dwt	
	Handysize	10,000–50,000 dwt	
Crude oil products	Long range 2 (LR2)	80,000–160,000 dwt	
	Long range 1 (LR1)	55,000–80,000 dwt	
	Mid range (MR)	25,000–55,000 dwt	
Gas	Liquefied natural gas (LNG)	Differentiation by volume (or cabin) capacity:	
	Liquefied petroleum gas (LPG)	Q-Max	250,000–300,000 m ³
		Q-Flex	200,000–250,000 m ³
		Standard type	100,000–200,000 m ³
		Small	<100,000 m ³
	Ethylene and other gas carriers	Differentiated by boiling point of the gas	
			Differentiation by tank (or cabin) type: Thin film cabin type Spherical Cabin type

Source: Created by the authors using various sources.

The various subsegments of the tanker sector are presented in **Table 2**. As can be observed, the loading capacity (deadweight) of subsegments may be overlapping.

The Bulk Freight Market

Freight rates in tramp bulk shipping are determined by the equilibrium (intersection) of supply and demand for freight services. In the maritime economics literature, the bulk shipping freight market is usually considered perfectly competitive (Norman, 1981), with freight rates constantly changing, according to the balance of demand with supply. There are thousands of vessels and hundreds of shipowners, offering the “homogeneous” service of sea transportation. Each shipping company only holds a relatively small market share and is thus considered a “price taker”—that is, no individual firm has a substantial proportion of the market, thus enabling it to affect freight rates. On the demand side, there are many buyers of the freight service, competing to hire the most economical vessel for cargo transportation. Shipbrokers match supply and demand and create a transparent market where information is efficiently disseminated. Even though large amounts of capital are required to enter the business, there are no other entry/exit barriers for new/already existing market participants.

In order to understand equilibrium freight rates, one needs to understand the supply and demand functions for freight services, their relative positions and how these evolve over time. The answer to these questions depends on the factors that affect supply and demand.

Supply of Sea Transportation

The supply component of sea transportation corresponds to the cargo carrying capacity of the fleet. In contrast to demand, supply is determined by the investment decisions of the independent market agents (the shipowners) involved in the maritime sector and therefore, is endogenous to the industry. Shipping supply increases through the ordering of new vessels, and decreases through demolition of existing ones.^d The delivery of a newbuilding order requires a time-to-build that can vary from 18 months upwards and depends on the prevailing market conditions, as well as shipyard capacity. Hence, in the short-term, shipping supply can be inelastic and adjusts sluggishly to changes in demand (Greenwood and Hanson, 2015; Kalouptsi, 2014). In this case, freight rates may increase rapidly in response to demand increases. In the short-run, supply can only increase either by taking ships out of lay-up, or by increasing the fleet productivity; the latter can be achieved by increasing the speed of vessels in operation, or shortening the time spent in ports. However, if demand is too strong, supply cannot adjust fully in the short run and freight rates skyrocket. In the long run, supply is not sticky and can adjust to the level of demand through the delivery of newly built vessels.

The response of freight rates to changes in demand depends significantly on the state of the freight market. In bear markets, when freight rates are low and expectations are dismal, part of the vessels in the fleet which are typically older, cannot cover their operating expenses (OPEX) and as a consequence are laid up. At the same time the (younger) fleet at sea is slow steaming to save on (voyage) costs. Thus an increase in demand is absorbed by vessels being brought back from lay-up and into service and by some of the slow-steaming ships gradually increasing their speeds. As a consequence, the impact of the increased demand on freight rates in this elastic segment of the supply curve is not significant, as opposed to its significant impact on the inelastic part of the supply curve described earlier.

^d Since supply (and demand) for freight services is measured in ton-miles, changes in the average speed of vessels will also affect supply in the market.

Owning and operating a fleet entails high operating and financial risks. Shipowners invest large amounts of capital in mobile assets (the vessels) which travel on the Earth's oceans, under high levels of operational risk, which includes adverse weather conditions, ship accidents, piracy, war risks, etc. To finance their investments, they usually rely on foreign capital, which include bank loans, bond issues, leasing, etc. Excess volatility of freight rates and vessel prices will increase their default risk; that is, the probability to be unable to honor the promised payments emanating from contractual agreements (repayment of bank loan, fulfillment of charter rates, bunkering, etc.). A ship can continue its operation only if freight earnings can cover OPEX and voyage costs. Otherwise, operating losses can drive the shipowner to put the ship into lay-up or even scrap it during prolonged periods of depressed freight markets, particularly for older, less efficient vessels.

Demand for Sea Transportation

Demand for sea transportation derives from demand for the goods being carried. For instance, demand for transportation of grains derives from demand for grains itself, which in turn depends on factors such as demographics, economic growth, changes in dietary and consumption patterns, etc. Equivalently, demand for iron ore comes from steel mills, which produce steel that is utilized in the construction of infrastructure projects. The latter, in turn, depends on industrial production and the growth of mainly the developed economies and the BRICS^e countries of the World.

Overall, world macroeconomic factors should be considered in order to understand demand for international seaborne trade. They include the business cycle of the world economy, which in turn is affected by factors such as the multiplier, time lags in decisions, stock-building, mass psychology, and random shocks. Trade elasticity of the world economy, that is, the percentage change in sea trade over the percentage change in industrial production, is a significant factor. This changes over time and depends also on the changing trade patterns in the world economy.

Commodity trade patterns are influenced by developments in relevant industries, for example, oil, gas, coal, agriculture, etc. Such developments may include changes in production technologies, the relocation of processing units or refineries^f, discoveries of new resources and/or depletion of others^g, changes in relative prices between commodities or (for the same commodity) between regions, concerns about security of the cargo transported^h, etc.

Seaborne trade patterns are also affected by seasonality patterns in relevant industries (Kavussanos and Alizadeh, 2001, 2002). For instance, more oil shipments are typically demanded in autumn and early winter, due to the need for heating. In metallurgical industries, where iron ore, coking coal and bauxite/alumina are transported, there are seasonal increases in demand in February and March, mostly in Japan, due to the financial year change. In agricultural industries, grain cargoes increase during the harvest seasons (spring and autumn).

In bulk shipping, demand is considered to be inelastic in the short term. The underlying reason is that the freight rate payable represents only a small part of the final price of the good transported, so only if a substantial change in the freight rate occurs, will demand for sea transportation possibly be affected. In addition, for most commodities transported in bulk, there is no economically viable alternative to sea transportation.

Market Equilibrium and Shipping Cycles

In bulk shipping, three types of equilibrium can be distinguished:

- Long-run equilibrium, which emanates from the long-run relationship between supply and demand, driven by shipbuilding and scrapping (demolition) and the changing long term trends in commodity trade patterns.
- Short run equilibrium, resulting from the interaction between global supply and demand. The time frame can be between a month and several months, a time frame that enables ships to move from one part of the world to another according to where the demand is emanating from. Over this time frame, factors such as lay-up rates, speed, bunker prices, seasonal trades, and fleet productivity are important.
- Momentary Equilibrium, which comes from the interaction between regional supply and demand. The time-frame in this case is less than a week, and concerns cargoes and vessels in the vicinity of one-week's travel to where the cargoes appear.

Three types of shipping cycles in freight rates and vessel values can be identified (Stopford, 2009): (1) the long-term cycle, which lasts for long periods of time (e.g., 60 yearsⁱ) and is driven by major changes in the economy, technological developments or regional factors; (2) the short-term cycle (also referred to as "business cycle"), which lasts from 5 to 10 years; (3) the seasonal cycle, which is observed within the year, prompted by the seasonality in demand for the sea transportation of goods (Kavussanos and Alizadeh, 2001, 2002).

^e BRICS stands for Brazil, Russia, India, China and South Africa.

^f For instance, oil refineries built near the market place rather than in oil producing countries are switching fleet requirements from product carriers to large crude carriers.

^g For instance, in the 1960s, crude oil was imported from the Middle East to the West. The discovery of Alaskan and North Sea oil resources reduced average haul; these areas being closer to Unites States and Europe, where demand comes from.

^h Disturbances to strategic sea-lanes impact average haul. For example, the closure of the Suez Canal increases distance between the Middle East and Europe from 6,000 to 11,000 miles, leading to a freight market boom. Other important passages include the Panama Canal, the Straits of Hormuz, the Bosphorus, the Straits of Malacca, the Straits of Gibraltar and the British–French Channel.

ⁱ Today, with the fast changing pace of technology, this would be shorter.

Figure 4 World fleet seaborne major and minor dry bulk trade development (billion ton-miles, 1990–2018). *Source: Figure created by the authors. Data derived from Clarksons SIN.*

Shipping is a highly cyclical business, with shipping cycles lagging behind the wider economic cycles. The short-term cycle is the one most commonly referred to as the “shipping cycle.” The stages of a shipping cycle include the market trough, the recovery, the peak and the collapse. During a cycle, integration between the shipping markets—newbuilding, sales and purchase, demolition and freight—is what reinstates equilibrium in the industry.

The sections that follow provide an insight into the specifics of supply and demand of the bulk sectors of the shipping industry, as well as their interaction through the various shipping markets.

Dry Bulk Sector of the Shipping Industry

The Derived Demand for Dry Bulk Sea Transportation—Dry Bulk Commodity Trades

The main commodities transported by ocean going dry bulk vessels can be classified into:

- the major bulks, which are iron ore, coal, and grains;
- the minor bulks, which include: bauxite, alumina, phosphates, steel, steel products, cement, sugar, rice, gypsum, nonferrous metal ores, salt, sulfur, forest products, wood chips, cotton, chemicals, fertilizers, cement, tapioca, jute, wine, coffee, and others;
- Specialist bulk cargoes, which have specific handling or storage requirements and include heavy lift, cars, timber, refrigerated cargo, etc.

The iron ore and coal trades are the two most important drivers of demand for dry bulk sea transportation. The coal trades include coking and thermal coal. Coking coal is used in metallurgical processes (e.g., in iron smelting to make steel), while thermal (or steam) coal is used for energy production (e.g., in generating electricity via steam). Iron ore and coking coal are the main components in the production of steel, which is massively used in construction, manufacturing and many other industries worldwide.

The grains trade is mostly regional, thus not driving major changes in the dry bulk sector. It depends on world population, feedstock, and human consumption. Minor bulk commodities are mostly used in construction and agriculture; thus their trade is mainly driven by industrial growth and world GDP growth. **Fig. 4** shows the World Seaborne Major and Minor Dry Bulk Trade development over the time period 1990–2018.

Iron Ore Seaborne Trade

Iron ore is mainly exported from Australia and Brazil (see **Fig. 5**). Their exports over the years 2000–10 reached approximately 70% of the world total seaborne iron ore trade. After 2010, given the increased exports from Australia, the two countries’ export shares jointly surpassed 80% of the world total seaborne iron ore trade. India had been the third main exporter until 2010, but a year later

Figure 5 World seaborne iron ore exports (million tons, 2000–18). *Source: Figure created by the authors. Data derived from Clarksons SIN.*

the Indian government started implementing a series of mining restrictions and iron ore export tariffs, in an attempt to create a framework to protect India's natural resources. From 2012 onwards, the third biggest iron ore exporter has been South Africa, followed by Canada.

The world seaborne iron ore trade increased by 230% during the period 2000–18. The key driver of this growth has been the increased demand for iron ore imports into China for the implementation of vast infrastructure and urbanization projects, as part of the Chinese policy for industrial growth. Chinese demand for high quality iron ore imports from Brazil, Australia, South Africa and Canada boosted demand, not only in terms of tons of iron ore transported, but also in terms of ton-miles, strengthening total demand in the iron-ore trades of the dry bulk sector—more iron ore cargo had to be transported over longer distances. From 2008 onwards, several countries implemented financial packages to stimulate infrastructure, one of them being China's CNY 4 trillion package. As can be seen in [Fig. 6](#), from 2009 onwards, around 90% of the world seaborne iron ore trade was transported into Asia, while approximately 70% of it specifically into China.

Coal Seaborne Trade

Two types of coal may be distinguished, based on their use: (1) metallurgical coal or coking coal and (2) thermal coal. They account respectively for approximately 25% and 75% of total world coal seaborne trade.

Coking coal is used in the process of creating coke. Coke, in turn, is used together with iron ore to produce iron and steel. Coke is a porous, hard black rock of concentrated carbon that is created by heating bituminous coal without air to extremely high temperatures.

Even though world seaborne coking coal trade has increased from 2000 to 2018, its increase is spikier and more volatile than the respective iron ore trade. China, the industrial growth of which has driven dry bulk trades during the last 15 years, has the third largest coal natural reserves in the world and is able to satisfy demand domestically. Only in 2009 did it start importing considerable amounts of coking coal, as seen in [Fig. 7](#), affecting the global coal trade balance and becoming the fourth largest coking coal importer after Japan, Europe and India. Moreover, China's coking coal imports derive mainly from price arbitrage practices, making them harder to predict. The major exporters of coking coal are Australia, Canada and the United States. As seen in [Fig. 8](#), Australia has been exporting more than 50% of the world seaborne coking coal over most of the years from 2000 to 2018, followed by the United States and Canada.

The second type of coal transported by sea is thermal coal or steam coal. This is ground to become powder, then fired into a boiler and burned for steam to run turbines which themselves generate electricity. Electricity is used either by electricity producing companies or directly by industry requiring electrical power. Examples of the latter include chemical industries, paper manufacturers, the cement industry, and brickworks manufacturing. Steam coal seaborne trade almost tripled during the years 2000–18, from 336 to 996 million tons. China and India increased considerably their imports from 2009 onwards, driving a surge in demand for steam coal and Indonesian exports. The main exporters are Australia and Indonesia. While South Africa used to be the third

biggest thermal coal exporter until 2013, Russia took over the third position ever since, increasing its exports from 13 million tons in 2000 to 118 million tons in 2018 (Figs. 9 and 10).

Grains Seaborne Trade

World seaborne grains trade has accounted on average for 11% of the world total dry bulk trade during the period from 1999 to 2018. It involves the transportation of wheat, coarse grains and soybean. Wheat is a cereal grain and a staple food worldwide. Its seaborne trade constitutes 36% of the world total seaborne grain trade. Coarse grains generally include cereal grains other than wheat and rice, such as maize, oats, sorghum, barley and various millets. Despite being used primarily for animal feed or brewing, varieties of coarse grains are also consumed by humans given their high nutritional value. The world seaborne coarse grain trade amounts to

Figure 10 World seaborne steam coal exports (million tons, 2000–18). Source: Figure created by the authors. Data derived from Clarksons SIN.

Figure 11 World seaborne grain imports (million tons, 2002–18). Source: Figure created by the authors. Data derived from Clarksons SIN.

38% of the world seaborne grains trade. Soybean is an annual legume consumed in vast quantities worldwide and also an ingredient for hundreds of chemical products. It accounts for 26% of the world seaborne grain trade.

Over 50% of the world's grain cargoes transported by sea are imported by Asia and Europe, while the remaining 50% is mainly imported by Africa, South and Central America, and the Middle East (see Fig. 11). The main grains exporter is the Americas, having exported on average 69% of the world seaborne grain trade flows over the years 2000–18. Other important export regions include Europe and Turkey, Russia and Ukraine, and finally Australia (see Fig. 12).

Figure 13 World bulkcarrier fleet development per vessel type (in million DWT, 1970–2018). Source: Figure created by the authors. Data derived from Clarksons SIN.

Supply of Dry Bulk Sea Transportation—Fleet, Freight Rates, and Market Integration

Figs. 13 and 14 present the dry bulk fleet development per vessel type during the years 1970–2018, in terms of deadweight capacity and number of vessels, respectively. The increase in fleet carrying capacity is impressive, from 64 million DWT in 1970 to 821 million in 2018—that is, almost 13 times in terms of deadweight capacity, and 4.5 times in number of vessels, in less than 40 years. It is obvious that the structure of the bulk carrier fleet has changed considerably over the years, with Capesize and Panamax vessels gaining share over Handysize ships, as a percentage of the total bulk carrier fleet capacity.

The fleet growth is greater during periods of increased demand for sea transportation and flourishing freight markets. As can be seen in Fig. 13, after 2002 the bulk carrier fleet capacity rose from 287 to 822 million DWT. The high demand for sea transportation of iron ore to Asia drove freight rates to historically high levels, with the Baltic Dry Index (BDI) skyrocketing from 1137.5 basis points in 2002 to 4510 points in 2004, and 7071.2 points in 2007 (see Fig. 15 for the historical evolution of the components of the BDI per

vessel category). Bulk carrier 5-year-old secondhand prices for all types of vessels followed suit, and also reached their highest levels in 2007, with Capesize vessels selling for more than \$150 million, Panamax reaching \$90 million, and Handymax and Handysize prices also peaking during this period (Fig. 16).

Expecting that China's economic growth would continue at the same or higher pace for the years to come, shipping investors kept ordering new vessels, thereby increasing world vessel tonnage. The bulk carrier 5-year-old secondhand price index reached the highest level of 422.8 points in 2007, from its level of 89.2 points in 2002 (see Fig. 16 for the historical evolution of 5-year old second hand prices per segment). The increase in the bulk carrier orderbook was impressive, and increased from 24 million deadweight tons in 2002, to 327 million in 2009 (Fig. 17). Since new orders usually have a delivery time of 18 months to 3 years, there is obviously a considerable time-lag between the peaks of demand and supply. In 2009, the bulk carrier orderbook was 78% of the total bulk carrier fleet, with the Capesize sector accounting for the largest part of it. This peak was reflected in newbuild deliveries in 2011 and 2012, their level surpassing the historical value of 100 million DWT (see Fig. 18).

Accordingly, during the period of booming markets, the demolition market was almost inactive. It was only in 2008 and 2009, during the global economic crisis, that demolitions recovered, reaching their highest level since 1970 in 2012, with a value of 8.3 million DWT (see Fig. 19). At that time, while freight and sales and purchase markets were at their lowest levels, with oversupply of dry-bulk capacity having already been created (newbuild deliveries were at their highest level), the demolition of old capacity could be seen as a potential relief to the markets. The inevitable collapse came in the latter part of 2009, and was a result of the choking off of world demand following the global economic crisis, coupled with the oversupply of vessels in the shipping markets. Ever since, freight rates and ship values fluctuate well below the levels seen prior to 2008.

The Wet Bulk (Tanker) Sector

The Derived Demand for Wet Bulk Sea Transportation—Commodity Trades

In the tanker sector, the main commodities transported are crude oil, oil products, liquid chemicals (such as caustic soda), liquefied gases (e.g., Liquefied Natural Gas/LNG or Liquefied Petroleum Gas/LPG), vegetable oils, and wine. As can be seen in Fig. 20, crude oil trades dominate the sector, followed by the trade of oil products, LNG, and Chemicals.

Crude Oil Seaborne Trade

Approximately 85-90% of world seaborne crude oil exports come from the Middle East, Africa, the Former Soviet Union (FSU) countries and Latin America (see Fig. 21), with the Middle East being by far the largest exporter, holding a 45% world export share. The main importers are South and Southeast Asia, Europe and the United States (see Fig. 22). Chinese seaborne crude oil imports from 2000 to 2018 quintupled, from 69 to 414 million tons, due to oil demand rising faster than domestic production, given the country's strong economic and refinery-capacity growth. China became an oil importer only in the 1990s, when its domestic oil production was not sufficient to cover demand.

Figure 20 Tanker sector major trades (in billion ton-miles, 1999–2018). *Source: Figure created by the authors. Data derived from Clarksons SIN.*

The world seaborne oil trade is driven by developments in the oil market, which is characterized by high volatility. Observing **Figs. 21 and 22**, one can distinguish three major downturns in the total world seaborne oil trade: one in 2002, a second in 2009 and a third in 2014. The first drop is attributed to the 9/11 terrorist attack which caused a severe decrease in oil prices. From 2002 to 2008,

Figure 21 World seaborne crude oil exports (in million tons, 2000–18). *Source: Figure created by the authors. Data derived from Clarksons SIN.*

Figure 22 World seaborne crude oil imports (in million tons, 2000–18). *Source: Figure created by the authors. Data derived from Clarksons SIN.*

the oil market experienced a boom, with oil prices increasing year after year, until the 2009 spectacular collapse in the aftermath of the Jeddah Energy Meeting in June 2008^j and the deepening global economic recession. In subsequent years, given the boom in US shale oil production and the weaker economic growth in China and Europe, the oil market has been highly volatile. In the interest of restoring oil market equilibrium, OPEC 2014 Conference Meeting in Vienna^k decided to maintain oil production levels at 30 million barrels per day, causing another sharp drop in oil prices.

^j Given their concerns about sharp increases in oil prices and their volatility, which threaten global oil market stability and sustainable economic growth, Ministers and representatives from many oil producing and consuming countries met in Jeddah, Saudi Arabia, on June 22, 2008. A Joint Statement by the Kingdom of Saudi Arabia and the Secretariats of the International Energy Agency, the International Energy Forum and the Organization of Petroleum Exporting Countries (OPEC) was the result of this meeting. In this Statement, participants agreed on the necessity of specific measures regarding the timeliness and adequacy of oil supply in the market, regulation and transparency in financial markets, quality, completeness and timeliness of oil data, etc. See OPEC Press release on www.opec.org.

Figure 24 World seaborne oil product imports (in million tons, 2000–18). Source: Figure created by the authors. Data derived from Clarksons SIN.

Oil Products Seaborne Trade

Seaborne exports of oil products mainly originate from Asia, Europe, the Middle East, North America and the FSU (see Fig. 23), while the main importers are Asia and Europe (see Fig. 24). Developments in the oil refining industry affect both crude and products trade. During the past decade, China and the United States have been increasing their refinery capacities, growing also their intra-regional products exports—from China to Southeast Asia and from the United States to North and Latin America. China's rapidly growing refinery capacity is associated with the growth in Chinese seaborne crude oil imports, while the same effect is less strong in the case of the United States, due to increased domestic crude oil production and low oil demand levels in recent years. The European products trade has experienced several shifts, prompted by significant changes in oil prices and inventories. The intra-European products trade accounts for over 70% of European imports.

Figure 26 World tanker fleet development per vessel type (in million DWT, 1970–2018). Source: Figure created by the authors. Data derived from Clarksons SIN.

Supply of Wet Bulk Sea Transportation—The Tanker Fleet Throughout Market Cycles

From 1970 to 2018, the tanker fleet doubled in number of vessels (see Fig. 25) and tripled in deadweight capacity (see Fig. 26), reflecting the increasing need for transportation capacity to match the demand for wet bulk trades. The firm tanker market in the early 1970s resulted in speculative investments in newbuild tanker vessels, which were delivered in the following years. In 1975, new deliveries reached their second historically highest level (for the period from the 1970s onwards - see Fig. 27), while the demolition market was almost inactive during the period 1970–74 (see Fig. 28). The oversupply of deadweight capacity and rises in oil prices in 1973 and 1979, brought the tanker freight market to a trough that lasted until 1987. During that period of low markets, there was a

Figure 27 World tanker fleet deliveries per vessel type (in million DWT, 1970–2018). Source: Figure created by the authors. Data derived from Clarksons SIN.

Figure 28 World tanker fleet demolition per vessel type (in million DWT, 1970–2018). Source: Figure created by the authors. Data derived from Clarksons SIN.

decline in total tanker fleet capacity as demolition skyrocketed to levels not since realized, and the newbuilding and sales and purchase market prices (see Fig. 29) collapsed.

The tanker market started recovering after excess capacity had been scrapped, rising to a new freight peak in 1989. Expectations for growing oil demand and high future demolition of vessels built in the 1970s led investors to place new orders. However, expectations were not realized and when new orders were delivered in 1992, they pushed the market to a new recession. During the 2000s, the tanker market flourished, driven by China's increased demand for oil imports to "fuel" its rapidly growing economy. The market boom lasted until the 2009 collapse (see Figs. 30 and 31), due to the deep, global economic recession and the 2008 Jeddah Energy Meeting's decisions to put a ceiling on oil supply, in an attempt to restore equilibrium in the market for crude oil.

Figure 29 Tanker vessels, 5 year old secondhand prices (in million \$, 1976–2019). *Source: Figure created by the authors. Data derived from Clarksons SIN.*

Figure 30 Baltic exchange dirty and clean tanker indices (index values, 1998–2019). *Source: Figure created by the authors. Data derived from Clarksons SIN.*

Figure 31 Baltic exchange dirty tanker time-charter equivalents (\$ per day, 2008–19). *Source: Figure created by the authors. Data derived from Clarksons SIN.*

After 2009, the market has been highly volatile during its course to recovery, affected by the weaker economic growth in China and Europe, the US shale oil production boom and OPEC's 2014 decision to prolong the ceiling on oil production levels. In 2018, tanker demolition hit the highest level since 1985, driven by the depressed freight market, the prolonged limits in OPEC oil cargoes and environmental regulation requirements regarding tanker vessels, which are costly to comply with.

Summary

The dry and wet bulk sectors of the maritime industry account for the largest carrying capacity of ocean going vessels, with containers coming third. It is thought that conditions of perfect competition prevail in bulk freight markets, with freight rates determined by demand and supply in each market. There are distinct submarkets within dry bulk and within tanker sectors, respectively. Albeit driven by common factors, such as the world economy and its economic activity, there are distinct factors in each submarket that should be analyzed separately in order to understand the dynamics of each market. This article has considered the main drivers of demand in each of the markets, including the commodities being transported and their characteristics. It also clearly identifies the types of vessels involved in each market and considers how the constituents of demand, supply, freight rates, and ship prices have evolved over time in each of the segments. In sum, it provides a brief and concise description of the dry and wet bulk sectors of the maritime industry.

Introduction

Despite *short sea shipping* (SSS) being widespread, consensus has not yet been reached about the limits of its nature. Although SSS is an international concept, one of its most cited definitions in the literature is provided by the European Commission (COM(95) 317): *The movement of cargo and passengers by sea between ports situated in geographical Europe or between those ports situated in non-European countries having a coastline on the enclosed seas bordering Europe*. In order to facilitate comprehension, this article will assume SSS to be short-range maritime transport for the movement of cargo and passengers, since this definition is widely accepted by transport stakeholders as distinguishing SSS from deep-sea transport.

Even though SSS is a *traditional concept* as it has always existed, it has gained special attention in the last 2 decades, mainly due to explicit support obtained from policy-makers in different regions, especially from the European Union (EU). The absolute predominance of road haulage over all other transport alternatives in Europe had already been identified as a significant problem in the first *European White Paper on Transport in 1992*. With the intention of finding alternatives to the congestion problems of European roads, the EU promoted its *Transport Policy* and the idea of *intermodality*, as a feasible solution for *door-to-door* transport (Medda and Trujillo, 2010). Hence, since the 1990s, through successive *White Papers on Transport*, European Transport Policy has supported the development of intermodal chains through SSS as a strategic measure to mitigate the negative effects for citizens (e.g., accidents, pollution, congestion, noise, bottlenecks, etc.) of the intra-community transport of commodities.

Far from being a regional concern, the previously mentioned negative consequences of land transport are recognized by the international community, and this reality has driven SSS to be of global interest. Likewise, increasing environmental concerns have reinforced the preference for SSS, since maritime transport has been shown to be a sustainable solution to meet transportation

needs (Medda and Trujillo, 2010). Thus, whereas in the EU, SSS has evolved toward Motorways of the Sea (MoS) (*White Paper: European Transport Policy for 2010*), Canada and the United States signed a *Memorandum of Cooperation on Sharing Short Sea Shipping Information and Experience* in 2003. The competitiveness and feasibility of SSS as the “trunk haul” of intermodal chains has been largely attended in the last decade by transport researchers in several geographical contexts beyond the EU: in Asia, America, and Australia, among others.

This body of research has frequently demonstrated that SSS is a convenient trunk haul for intermodal transport because it enables not just the social costs derived from high traffic concentration on land to be reduced, but also the private costs for transport stakeholders (i.e., shorter traveling distances). Thus, when SSS is a *feasible stretch* for the intermodal chain, this is often the leading option for policy-makers mainly due to: its low requirements in terms of infrastructure investment, its capacity to reach ultra-peripheral regions, and because it can take advantage of economies of scale by using vessels (this also affects the environmental costs). All these motives are very convenient regardless of the location of transport services; however, they are especially significant in regions where transport by land is particularly difficult, the maintenance costs of corridors are high in relation to the size of the economies of the countries, crossing borders by road involves high costs, and there are incomplete connections in the road network. Therefore, despite scarce attention paid in the literature to intermodality in emerging markets, SSS is also put forward as a convenient solution for freight transport in those regions.

As a result of the promotion of SSS since the 1990s, numerous studies and projects have been financed by the EU and by countries from other regions, with the intention of identifying and addressing the weak points of intermodality through SSS. One of the most significant conclusions of these studies was the identification of the weakest attribute of the intermodal chains: the time invested in the transport (Martínez-López et al., 2015a; Suárez-Alemán et al., 2014). This finding was reached through analysis from very diverse points of view. However, the modal choice studies did not just identify this improvement point, but also revealed the negative perception of SSS compared to trucking on the part of shippers: that is, SSS is an outdated, slower, rigid, and complex alternative from an administrative point of view, in addition to being less reliable (Medda and Trujillo, 2010).

As a consequence of these results, enormous efforts were made by policy-makers to reverse this perception. In this regard, the simplification and standardization of bureaucratic processes associated with loading cargoes in European ports was especially successful. In parallel, considerable attention was paid to research studies focused on minimizing the time invested in intermodality through SSS. Among them, it is worth noting the studies related to the feasibility of operating *High Speed Crafts* (although this possibility was finally ruled out due to the high associated costs), the port efficiency impact on intermodality (Suárez-Alemán et al., 2014, 2015), and the identification of the most advantageous routes to operate under SSS conditions (Martínez-López et al., 2015a).

Regarding port performance, the insights drawn from these analyses are highly significant: SSS vessels in the North and Baltic seas were found to spend up to 40% of their time in ports and half of this time was unproductive. As a consequence, specific recommendations were made: to improve cargo-handling efficiency in ports and increase energy efficiency for the SSS fleet by reducing waiting times in port (Suárez-Alemán et al., 2015). In such a way, the port's role in intermodality was developed over time, from the initial nodes for the transport networks to the current situation where they may be regarded as consolidation centers for cargo shipments.

Early in the development of SSS in Europe, considerable efforts were made to identify the most promising potential corridors in which to establish SSS services. It has been widely demonstrated that the relative competitiveness of intermodal transport against road is determined by a combination of the operating and technical features of the transport modes, customer requirements, and geographic characteristics (Medda and Trujillo, 2010). Despite this, the EU established as a priority the geographical definition of the maritime corridors to operate under SSS conditions. Thus, the research studies firstly concluded distance thresholds (general recommendations: maritime distances ranging between 834 and 1400 km and a minimum threshold of 1385 km of land distance between origin and destination points) or particular routes that ensure the “intermodality success” of SSS against road haulage (Martínez-López et al., 2015a).

To reach these findings, load patterns, the features of SSS services, and the technical features of the vessels at the time of the study were all assumed as fixed parameters. As a consequence, optimum route selection was based on their fit with the operating features of the existing fleets in Europe (Martínez-López et al., 2015b). This practice was commonly accepted.

As a consequence of this, most of the initial projects investigating the competitiveness of intermodal chains involving SSS considered solely rolled cargo (i.e., trucks) as cargo units. By so doing, only the roll-on roll-off traffic conditions for the vessels (RO-RO and RO-PAX vessels/ferries) were included in these studies. This choice of the cargo unit was also supported by the idea that RO/RO vessels were the most suitable for intermodal transport through SSS (the lowest times for the cargo-handling operations). In addition, this assumption also involves a political intention to reinforce the idea of complementing, instead of substituting for truck transport through intermodality. Nevertheless, this argument was not sufficiently convincing to rule out other compatible cargo units under intermodality. For that reason, subsequent studies included containers as cargo units and, therefore, feeder vessel activity was included among the intermodal possibilities (Martínez-López et al., 2015b).

In 2003, as a consequence of the *Van Miert Report*, the European Commission reviewed the extension of the *Trans-European Transport Network* (TEN-T) (revision of TEN-T guidelines 2004, Decision No 884/2004), by including four maritime corridors under a new concept: *The Motorways of the Sea*: that is the *Motorway of the Baltic Sea*, *Motorway of the Sea of Western Europe*, *Motorway of the Sea of South-East Europe* and *Motorway of the Sea of South-West Europe*.

Despite the efforts made by various administrations and political institutions with transport responsibilities, it is commonly accepted that the development of SSS has not currently achieved the success expected (Suárez-Alemán et al., 2015). Beyond the

wrong assumptions about the expected behavior of transport decision-makers (based on the value added to the freight, the size of the cargo unit, the type of shippers, etc.), there are several operative reasons for this. The following are notably cited in the literature: the low frequency of transport services, slow speeds, and the lack of efficiency of freight transitions between transportation modes. In addition, numerous authors have also pointed out the policy-makers' responsibility for the imbalance in (Gesé and Baird, 2013):

- the internalization of external costs between SSS and the road (considerable public funds have been uniquely channeled into the development of roads and railway infrastructure);
- the progressive deregulation of road freight; and
- the environmental requirements demanded by the environmental regulations for each transport mode (Cullinane and Cullinane, 2013; Hjelle, 2014).

The latter involves an environmental regulation that is less demanding and has had a slower evolution in the maritime sector than the land normative. Consequently, the technological development in the reduction of pollutant emissions has clearly been slower in the maritime sector (Cullinane and Cullinane, 2013). This fact, along with the characteristics of SSS vessels (small and fast vessels; Martínez-López et al., 2015b), has motivated that the environmentally friendly label traditionally given to SSS in comparison to other transport systems has recently been under discussion (Hjelle, 2014).

Hence, there is a perception that the regions, which have politically supported the development of maritime transport, have, however, transferred the responsibility for the success of intermodal transport (a matter of general interest for citizens), to private initiatives, which not only must take decisions about the operative and technical characteristics of the fleets and facilities (with considerable influence on intermodal performance), but also cope with an initially disadvantaged position with regard to road transport (Martínez-López et al., 2015b, 2018).

The following sections of this article will analyze more closely some of the issues addressed in this introduction. This introduction is firstly followed, however, by a review of the state of the MoS and their implications. Afterwards, there is a brief discussion about the current sustainability of the intermodal chains that involve SSS, by considering the necessary technology to improve the environmental performance of seaborne transport. This section also includes the main challenges for SSS due to its current technological limitations.

The Motorways of the Sea (MoS)

The MoS Concept and Main Milestones in Its Evolution

The MoS concept did not formally appear in European Transport Policy until 2001 (*White Paper: European Transport Policy for 2010: Time to Decide*, 2001). However, although the concept is quite clear, no formal definition was provided. The MoS are introduced in the European Transport Policy as a wider concept than SSS, which attempts to respond with high effectiveness to the initial aims of seaborne transport in the EU: alleviating congestion and bottlenecks in the European road and rail networks through modal shift. Thus, the MoS not only involve the maritime corridors of the chains, but also imply their integration into "door-to-door" transport by including all necessary services into the modal shift in ports. Consequently, the MoS concept represents greater influence on the intermodal chain, with wider implications for the overall service (Medda and Trujillo, 2010). This new reality forces improvements on modal integration, administrative procedures among maritime regions, environmental performance, modal shift operations, etc.

Since then, the MoS concept has evolved within European Transport Policy through various promotional programs and legislative events. One of the most significant milestones in the development of the MoS was its inclusion in the TEN-T by the European Commission (revision of TEN-T guidelines 2004, Decision No 884/2004). The revision of the TEN-T guidelines 2004 was carried out according to the *Van Miert Report* (2003), which recommended as a priority the inclusion of the MoS in the TEN-T guidelines and its implementation in the *Marco Polo program* (the European program to reduce transport pollution through alternatives: in this case to support new SSS services).

The Van Miert Report defined four MoS corridors (the *Baltic Sea*—linking the Baltic Sea region with Central and Western Europe, the *Sea of Western Europe*—the Atlantic arc from the Iberic Peninsula toward North and Irish seas, the *Sea of South-East Europe*—connecting the Adriatic Sea with the Eastern Mediterranean, and the *Sea of South-West Europe*—linking the western Mediterranean with the corridor of the *Sea of South-East Europe* and the *Black sea*) to be integrated into the TEN-T, and that member states should support links between them, in accordance with their interests.

Thus, through the inclusion of the MoS into the TEN-T in 2004, a legal and financial context was provided for MoS activities (European Commission, 2017). In the call for proposals for TEN-T 2005 a number of MoS studies were funded, most aimed at identifying the most promising maritime routes and forecasting the cargo flow attracted by the proposed service. Even though the Marco Polo program began in 2003 with the aim of improving the environmental performance of the freight transport system through the reduction of road congestion, this did not include specific actions for MoS until the Marco Polo II (Regulation 1692/2006, updated by Regulation 923/2009) program (2007–13). Despite this retardation, this has been the main support program to develop the MoS concept.

In 2007, the MoS attained a new role in EU policy by being considered as one of the five axes to promote international exchange, trade, and traffic between the EU and its neighboring countries (COM(2007) 32: *Extension of the major trans-European transport axes to the neighbouring countries*). In the same year, the European commission published a report about the state of the MoS (COM(2007)

606: *The EU's freight transport agenda: Boosting the efficiency, integration and sustainability of freight transport in Europe. Report on the Motorways of the Sea: State of play and consultation*). Among other conclusions, the report proposed the creation of a one-stop help desk (the MoS Help Desk launched by the Trans-European Transport Network Executive Agency—TEN-T EA—and Executive Agency for Competitiveness and Innovation—EACI—in 2010) that could provide information about the financing of MoS projects and the establishment of specialized commission executive agencies to follow the TEN-T and Marco Polo project proposals.

In 2010, the *Europe 2020 strategy for smart, sustainable and inclusive growth* (COM(2010) 2020) included energy and climate targets that affected the MoS projects in the TEN-T framework. The 2013 work program: *Annual Report of the European Coordinator for the Motorways of the Sea* (Valente de Oliveira, 2013) also identifies sustainability as part of the general aim of the TEN-T MoS network: including the use of liquefied natural gas (LNG) as an environmental trend. In addition, as part of the *Europe 2020 strategy*, the communication launched on 2009 (COM(2009) 10) about the establishment of a European maritime transport space without barriers was developed. The communication proposed harmonizing and simplifying administrative procedures in SSS through the following actions (among others): the simplification of customs formalities for transporting goods between EU ports; the simplification of port reporting formalities (Directive 2010/65/EU), creating an “e-maritime” system for electronic data transmission; and the establishment of the *national administrative single windows* for port formalities.

In 2013, the TEN-T guidelines were revised again (EU Regulation No.1315/2013). This revision established the *Connecting Europe Facility* (CEF) as one of the funding instruments for TEN-T. The CEF Regulation (1316/2013) defines the Core Network of transport infrastructure: nine *core network corridors* (CNCs) start or finish in a port. In such a way, the MoS are the seaborne stretches of these corridors.

Since the end of the Marco Polo II program (2007–13), the CEF is the only instrument that can finance MoS projects. From 2014 to 2018, 46 MoS projects were funded under the CEF program. Thus, the CEF and the *European Fund for Strategic Investment* (EFSI) are the sources of EU financing for the transport infrastructure projects (2014–20).

Current Situation of the MoS and Policy Trends

According to the *detailed implementation plan* (DIP) (Simpson, 2018) provided by the European Coordinator for the MoS, the MoS in 2015 moved nearly 59% of all maritime transport of goods to and from European ports. This shows the key role that the MoS connections have to ensure the competitiveness of the European intermodal chains. In 2017, more than 800 regular RO-RO and container services were operating in the European transport network, with more than 400 calls from different EU ports, and connections with hundreds of ports around the world.

Even though a significant amount of tramp services are operating in the SSS regime in Europe, the feeder and RO-RO shipping (RO-PAX/ferries as well) show the greatest relevance due to their suitability for securing a modal shift. Consequently, they have essentially been the focus of the MoS investments. Since 2001–18, accumulated EU funding of EUR 857.5 million was targeted at boosting MoS projects (essentially *TEN-T* and *Marco Polo* programs, but also through others like *Interreg*, *Horizon 2020*, etc.).

The most important corridors for container traffic in the EU are as follows (European Commission, 2017):

- In the North of the EU: between the Baltic Sea and the North Sea, the services between continental Europe in the North Sea area, and the transport between the Republic of Ireland and the United Kingdom.
- In the South of the EU: intra-Mediterranean services and between the Black Sea and the Mediterranean.

Since 2002, the number of companies involved in carrying RO-RO cargoes has been decreasing, whereas the size of vessels has been increasing in all regions of the EU (European Commission, 2017). In 2013, the Mediterranean offered the highest number of SSS services for RO-RO cargo, followed by the Baltic Sea and the North Sea.

Despite the recognized relevance of maritime transport in Europe, the European Commission report: “Motorways of the Sea: An ex-post evaluation on the development of the concept from 2001 and possible ways forward. Final Report” (European Commission, 2017) assessed the effectiveness of the MoS projects for the period 2001–13 as “mixed,” by making a reference to the scarce contribution of the MoS to road congestion reduction to date. The industry’s evaluation of the MoS policy with respect to the promotion of modal shift was even more categorical. It was suggested that a disadvantage exists for MoS in relation to their competitors (moving cargo by road or rail) due to the additional regulatory and administrative obstacles (European Commission, 2017).

The limited contribution of MoS to the modal shift from road to sea has led to not only an exhaustive revision report about MoS results (European Commission, 2017), but also to a DIP provided by the European Coordinator for MoS in 2018 (Simpson, 2018). Among other points for improvement, the reports mention that:

- scarce attention was paid to modal shift targets by the MoS projects (predominantly these were simply related to market conditions and administrative obstacles); and
- the absence of road transport operators and small and medium enterprises (SMEs) in most MoS projects. This is particularly noteworthy given the objectives inherent for the MoS in European Transport Policy.

These circumstances, along with the proven fact that the EU subsidies by themselves are insufficient to maintain the interest of shippers in the MoS option, leads observers to consider that the intermodal chains through MoS have not reached the necessary level of effectiveness to be a clear alternative to the road mode for freight transport in the EU.

In light of the earlier, the MoS reports (European Commission, 2017; Simpson, 2018) concluded that there exists a need for a more holistic approach, by covering the whole freight logistics chain, in order to enhance intermodality. In that sense, it is remarkable how few MoS links are currently integrated into the *TEN-T CNCs*. The current corridors are land-based corridors that simply start or finish in the ports. The role of the ports in the *TEN-T* network necessarily must be modified in order to adequately integrate seaborne transport into the nine *CNCs*. The new role of ports must be as a center of consolidation of the load (intermodal node). This point is one of the most recognized improvement points in the development of the MoS, since this involves a wider discussion about the current classification of the ports in the *TEN-T* network (core and comprehensive ports—Regulation (EU) No 1315/2013) and the implications of this for the funding of MoS projects.

The current system of port classification has determined the funding priorities for the MoS projects (CEF program); this being one of the reasons why many peripheral regions and islands have not only been excluded from the network planning and transport maps of the *TEN-T*, but also why despite the importance of their maritime routes for local trade (the routes are connected through outside ports of the core/comprehensive list), they were largely absent from the projects funded from MoS funding programs (Simpson, 2018). Consequently, there is a consensus about the need to extend the current *TEN-T* corridors by reconsidering the current port eligibility criteria (with considerable difficulties applying across all ports, with great contextual variety).

Finally, further trends for the SSS and ports in the EU were provided by the European coordinator for MoS (Simpson, 2018), who highlighted three development pillars as key priorities for SSS and ports in the following years:

- Environment
- Integration of maritime transport in the logistics chain
- Safety, traffic management, and the human element

Environmental Sustainability and Short Sea Shipping

Traditionally, maritime transport was considered a means of sustainable transport. This assumption was mainly supported by the positive effects on costs of the economies of scale to be reaped in the utilization of vessels and because the evaluated pollutants were solely the greenhouse gases (mainly just CO₂ emissions) in most cases. However, the assessment is not so favorable when acidifying substances or ozone precursors are analyzed (Cullinane and Cullinane, 2013; Hjelle, 2014). This performance is even more disadvantageous when the analysis is carried out for SSS conditions, due to the technical and operational characteristics of SSS vessels (fast and small ships, along with the modal shift necessary for door-to-door transport) that generate higher emissions per ton and kilometer (Martínez-López et al., 2018).

As a consequence of the results obtained in recent evaluation reports, numerous authors are demanding special attention be paid to SSS sustainability and rejecting the *self-evident idea* of SSS as an environmentally friendly means of transport. In 2010, in a revision of exhaust emissions for Norwegian domestic maritime transport, the relevance of the NO_x, CH₄, black carbon emissions, and particulates in the SSS was confirmed (Nielsen and Stenersen, 2010). Along the same lines, the European Environment Agency (EEA) concluded in 2013 (Technical Report No. 4/2013) that the NO_x emissions for European maritime transport will reach the same level as land transport NO_x emissions by 2020. Taking into account the local and regional impact of this pollutant, this finding is especially concerning for the SSS in Europe, due to the virtually nonexistent regulations (Bengtsson et al., 2014).

Even though certain EU zones are classified as “Sulfur Emission Control Areas (SECAs)” (the Baltic Sea, the North Sea, and the English Channel, with the Mediterranean shortly expected to join) by the *International Convention for the Prevention of Pollution from ships* (MARPOL 73/78; Annex VI: Regulations for the Prevention of Air Pollution from Ships), this classification simply involves limitations of SO₂ emissions (SECA zones); while no NO_x is restricted (Bengtsson et al., 2014). In this sense, despite the reaction of the EU to these environmental results, no specific European regulation has limited the NO_x emissions in maritime transport to date. This issue has contributed to the increasing criticism about the unbalanced treatment of sustainability among transport modes by policy-makers.

Evidence of this inequality is the different evolution of the European restrictions for environmental sustainability in road transport in relation to seaborne transport (Cullinane and Cullinane, 2013; Brynolf et al., 2014). The *White Paper on Transport 2011* drew up targets for maritime transport greenhouse emissions that were specified in 2013 through a “step” strategy (COM (2013) 479). Since then, only the first step has materialized through the setting up of *Monitoring, Reporting and Verification* (MRV) systems for CO₂ emissions in vessels (the first reporting period scheduled was for 2018). In addition, in 2016, the EU, through the Directive (EU) 2016/802 of the European Parliament, limited sulfur emissions in all European territorial seas and Exclusive Economic Zones from 2020, but the restrictions simply met the International Maritime Organization (IMO) requirements for the SECA.

This regulation for seaborne transport contrasts with the evolution of standards for land-based industries. Since the 1990s, Euro standards (from Directive 91/542/EEC, amending Directive 88/77/EEC) have driven the environmental requirements for road transport in Europe. With an increasing level of restriction (from Euro I to Euro VI) for all main pollutants (including NO_x and particle pollutants targets) the technological development of trucks has adapted over time to meet these standards.

Even though the most restrictive standard of the *International Convention for the Prevention of Pollution from Ships* (MARPOL 73/78; Annex VI: Regulations for the Prevention of Air Pollution from Ships) was imposed on the European seas (Emission Control Area—ECA zones—which restricts SO₂ and NO_x emissions at the same time), the disadvantage in terms of NO_x and SO₂ emissions for

seaborne transport compared to trucking is notable. Moreover, suitable technological alternatives used in combination with marine bunker fuels and different marine engines to meet the ECA requirements involve significant disadvantages (Brynolf et al., 2014; Martínez-López et al., 2018). Specifically, the abatement of NO_x emissions currently requires: the use of Selective Catalytic Reduction (SCR) systems, which are compatible with petroleum fuel engines, the use of expensive fuels (marine gas oil—MGO), or the use of gas engines. The first option has to cope with the ammonia slip problem or, where gas engines are fed by LNG, methane slip then becomes an issue. This is especially significant for SSS and, thereby, arises as a particular problem (Martínez-López et al., 2019).

Despite international opinion supporting LNG as a feasible solution for SSS environmental problems (the EU has committed itself to establishing infrastructure that will allow LNG to be available to ships in all of its 144 maritime and inland ports by 2025), it is worthwhile noting the current difficulties associated with the use of LNG in ships. On the one hand, this gas by itself remains far from providing emission levels close to Euro VI standards (trucking), and, in addition, recent publications highlight the fact that expected maintenance savings, along with the reduced LNG price, are insufficient to balance the capital costs associated with retrofitting. Finally, the lack of specific regulations and technical solutions for the methane slip from LNG engines has emerged as an additional problem (Brynolf et al., 2014; Martínez-López et al., 2019).

Shipping Today—The Relation Between Shipping and the Natural Environment

The sea provides the infrastructure for shipping, but it is also a very important part of the natural environment, providing all kinds of ecosystem services to man. More than 70% of the surface of the earth is covered by oceans, and life on earth is completely dependent on the function of oceans. The sea plays an important role in the hydrological cycle but also in the geochemical cycles of carbon, nitrogen, sulfur, and other elements. The sea is used by man for many different purposes other than shipping, like fishing, food production, energy production (wind, waves) as well as oil/gas and mineral extraction. Since “what is below the surface is not visible” has been treated as a truth for a long time, the sea has traditionally been used for waste dumping and objects lost into the sea have not been recovered. When technology allows more sophisticated exploration below the surface and the environmental impacts of dumped or lost materials like plastic objects or fishing nets, becomes obvious, this has become an increasing problem. The competition between the different interests of using the sea can also be a source of conflicts.

Shipping is a large sector globally, more than 90% of goods transport is performed by sea, and in spite of the fact that shipping is the most energy efficient means of transport in terms of energy used per ton km (or ton nm), it also causes impacts. These include impacts not only on the natural environment but also on health, crops, and the built environment. Emissions from shipping are regulated in various ways, locally in ports and fairways, as well as nationally with the framework for international shipping regulations by the International Maritime Organization (the IMO). The use of marine spatial planning (MSP) has been developed as a tool to be used in order to avoid problems that can arise from multiple activities in a marine area.

Emissions to Air and Impacts—The Role of Fuel

The main part of emissions to air from shipping is related to the fuel. Traditionally, combustion engines using heavy fuel oil (HFO) or marine gas oil/marine diesel oil (MGO/MDO) in diesel engines, have been dominating. Also dual fuel engines with the possibility

to run on different fuels [diesel/liquefied natural gas (LNG) or diesel/methanol], or diesel electric engines are used. The use of fossil fuel is associated with emissions of carbon dioxide, but there are also other combustion-related emissions that have environmental impacts.

There are international regulations for shipping emissions to air regarding sulfur (in terms of the fuel content) and nitrogen (in terms of emission of nitrogen oxides related to engine speed). For carbon dioxide (CO₂), the reduction has been handled in terms of energy efficiency (EEDI, energy efficiency design index) for new built ships.

Greenhouse Gases and Growing Shipping

Greenhouse gases (GHG) are gases in the atmosphere that absorb infrared (heat) radiation, keeping the temperature on earth more even through the hours of the day and by this making the earth habitable. The most abundant GHGs are water vapor and CO₂ but there are many more heat-absorbing gases, both naturally occurring and anthropogenic.

The CO₂ is part of the natural carbon cycle between soil and water. However, increased use of fossil fuels after industrialization, combined with a growing population has increased the amount of carbon available in the cycle and thus of CO₂ in the atmosphere. Emissions of more strongly absorbing gases like methane add to the effect. The most discussed result is global temperature increase but the carbon dioxide also leads to increased carbonate contents and increased acidity of the oceans.

In the *Third IMO GHG Study 2014*, it was estimated that GHG emissions from international shipping in 2012 accounted for about 2.2% of anthropogenic CO₂ emissions and that the emissions may grow by between 50% and 250% by 2050 (Smith et al., 2014). The Paris agreement with a very tight goal for CO₂ reduction is not applied to international shipping, since the IMO has the responsibility for the shipping sector. The IMO has attempted to decrease the CO₂ emissions by regulations in terms of demands on energy efficiency for new ships (Energy Efficiency Design Index, EEDI). This has been shown not to be sufficient to obtain a decrease, especially given expected future increases in sea transport, and the IMO in 2018 set a goal of a CO₂ decrease by 50% by 2050 and of zero emissions “within this century” (IMO, 2018).

Sulfur Emissions

Sulfur oxide emissions from shipping are mainly due to the use of fuel with high sulfur content. HFO, that has for a long time been a dominating fuel for larger ships, contains various, and sometimes high, amounts of sulfur—up to 4%, while MGO usually has low-sulfur contents and fuels like LNG or methanol are sulfur-free. The sulfur is a contaminant in the fuel and fulfills no function for the ship engine and the sulfur oxides formed in the combustion are forming a strong acid when dissolved in water. High sulfur content also promotes the formation of particles in the exhausts. The permitted sulfur content has been lowered in steps both globally and in special “Emission Control Areas” (ECA). From 2020, the global limit is 0.5%. In ECAs in the Baltic Sea and North Sea and in North America, the limit is 0.1% (Smith et al., 2014).

The sulfur regulations may be met by using low (or no) sulfur fuel or by continuing with high sulfur fuel and combining this with emission abatement on board. Emission abatement can be performed by washing the sulfur into liquid, by the use of a “scrubber.” This can be done using seawater that is discharged into the sea after use, “seawater scrubbing,” or by using a closed-water/chemicals circuit on board, “closed-loop scrubbing.” In addition to sulfur these can be various hydrocarbons and metals. Seawater scrubbing thus moves the contaminants from air to the ocean in a concentrated form. The impact of this is not fully understood, and the method has been questioned. For both scrubber alternatives, a sludge that has to be treated or disposed of on land is resulting, setting demands on port reception facilities. The scrubber comes with an investment cost as well as a need for space and increased weight on board. The economics of the alternatives varies depending on the fuel price at a certain time. The fuel prices in 2018–19 have been low, making scrubbers attractive, and a large number have been installed. Use of sulfur-free fuel like liquid natural gas, LNG, is another alternative that is increasing.

NO_x

Nitrogen oxides are formed in the combustion, mainly due to the nitrogen (N) and oxygen contents in the combustion air (the N₂ contents in air is around 79%). At the high-combustion temperatures, the nitrogen forms oxides that are both acidic and contributing to the formation of secondary air contaminants like ozone. NO_x formation in engines is thus dependent on the combustion conditions as well as the operational mode of the ship. Low-NO_x emissions are observed using methane (LNG or LBG) or methanol, but still the combustion technology and operation of the engine are important to achieve this. Exhaust gas recirculation (EGR) is one technology that reduces the emissions. NO_x can also be removed after combustion by a catalytic technology, SCR, where the NO_x is reduced back to nitrogen gas. A limitation of the SCR technology is that it can only be used when the exhaust gas is warm enough, (> 200°C) and thus the NO_x emissions will be high when the engine is started up, and often also for some time after leaving port.

Particles

Particles are formed in the combustion and also in the exhaust gas (“secondary particles”). There is a strong correlation between sulfur contents of the fuel and particle formation. The impact of particles varies somewhat with the particle size.

Large particles are deposited close to the source and are visible, “soot.” Small particles (up to 10 μm , PM_{10}) are not as visible, but are spread over larger areas and may constitute a health hazard. Particles are absorbing heat and “black carbon” particles are a contributor to global warming. Particles can also act as catalysts for the formation of secondary air pollutants.

Measurements of particle emissions are mainly performed in terms of mass (g/kWh). However, this is a poor indicator for the small particles, where the number of particles of low weight may be large, but with a small total mass.

Fuel Alternatives

In order to decrease emissions, various types of fuels have been suggested and tested as alternatives to HFO. Fossil-based alternatives are MDO and MGO with low-sulfur content, LNG, and methanol. Renewable alternatives can be biodiesel but also liquefied biogas (LBG), methanol made from renewable material and hydrogen (Brynolf, 2014; Balcombe et al., 2019). Recently, also ammonia (NH_3) has been proposed as a shipping fuel. The production of synthetic fuels from (renewable) electricity and CO_2 , “electrofuels” is also being investigated. Electricity is increasing as an energy carrier for ships, especially in the short sea-shipping segment in the form of hybrid, but also as fully electric, vessels.

The outcome of a change of fuel in terms of emissions varies depending on the fuel and the propulsion technology. Converted traditional engines can be used, but engines developed and optimized for the specific fuel may give better performance. There are two principal kinds of fuel in terms of storage, liquid and gas. A change from liquid to a gaseous fuel sets demands on fuel handling systems and also on regulations.

The fuel alternatives are in many cases the same as discussed for other transport sectors. However, for shipping some additional focus has been on methanol and recently also on ammonia, two chemicals that are widely used in industry and having a well-developed global production and distribution. The production of both is today based on natural gas. However, the production may be using renewable electricity, “electrofuel.” In this production hydrogen is an intermediate step. Methanol and ammonia can also be used as a “hydrogen carrier” from which hydrogen can be released for use in fuel cells or engines. Also “biomethanol” can be produced from all kinds of raw material, including waste.

Methanol, (CH_3OH), is liquid at ambient temperature, which makes it easy to store and handle. Methanol can be used as a marine fuel in diesel engines as well as in Otto engines. In the diesel engine, a small amount of other fuel like diesel, “pilot fuel,” is needed for ignition. Dual-fuel diesel engines running on methanol/diesel are in use in some ships, for example, a RoPax Ferry between Sweden and Germany. Methanol is toxic to man, setting demands on handling. However, it mixes with water and is biodegradable, making spills into the environment of low and local impact.

Hydrogen has long been considered as a future fuel and is possible to use in both combustion engines and fuel cells. The only direct emission is water vapor when used in fuel cells. However, for the use of hydrogen to reduce climate impacts it is important that hydrogen is produced from renewable resources or from nonrenewable resources in combination with carbon capture and storage. The fuel cell technology has matured and reduced in cost, but there are still challenges, such as the cost of the fuel and with hydrogen storage and infrastructure. Hydrogen gas has a very low volumetric energy density and needs to be compressed, liquefied or bound to other molecules or substances to increase energy content per volume. One way to store hydrogen is to bind the H_2 molecule to nitrogen and form ammonia.

Ammonia (NH_3) is a compound consisting of only nitrogen and hydrogen. Due to the lack of carbon in the molecule, ammonia has recently (2019) been proposed as a future energy carrier for many different purposes, including shipping. Ammonia is a gas at room temperature. (Not to be mixed up with the aqueous solution sold for household purposes). Ammonia as a fuel is not yet tested in modern engines, although engine development has been started. Ammonia has been used as a refrigeration liquid, but is often avoided due to safety reasons. A release of ammonia to air is toxic to humans and has an unpleasant smell in low concentrations, which will be an issue in handling. However, ammonia is quickly decomposed, so the effect is local.

Life Cycle Impact of Fuel

Although the emission regulations only apply to the operation of the ship, the environmental impact is also dependent on what happens upstream, in the production and distribution of the fuel to the ship. A fuel that has low emissions in use, may need a large effort in production, including phases like harvesting (biofuels), transport, reforming, and purification processes. The production of renewable fuels may also include use of fossil energy, making the gain in GHG savings smaller.

The widespread use of HFO in shipping has been the result of a competitive price of fuel. Also the total energy used for production of the HFO is low, adding to the competitiveness. Production of renewable fuels requires more energy input and processing, resulting in a higher price compared to HFO, often 2–3 times higher. A challenge for future renewable fuels is to develop production at low energy input and cost.

Examples of environmental impact and energy use in a well to propeller perspective for some fuels as compared to HFO are given in Fig. 1.

Figure 1 Properties of some alternative fuels from “well-to-propeller” (production and use of fuel) in comparison to HFO (= 1) in terms of total energy input and emissions. Source: Compiled from Brynolf (2014).

Propulsion Alternatives

Electricity/Batteries

The development of electrical propulsion for vehicles has made electricity an interesting energy carrier also for ships. There has been a use of electric propulsion on board ships for a long time as “diesel-electric” propulsion, where the diesel engines generate electricity that is used for propulsion. For short distances, passenger ferries, etc., all-electric propulsion with batteries is coming into use. The use of batteries for onboard recovery and storage of energy is used.

Battery-electric propulsion has a very high-energy efficiency and roughly half the energy is needed for the same propulsive power compared to the use of diesel in internal combustion engines. Despite the higher efficiency, the battery-electric propulsion system is only viable for short distances unless considerable improvements in the energy density of batteries are achieved. Another way to reduce the climate intensity of the propulsion system is to harvest energy directly from the wind and sun (Brynolf et al., 2018).

Wind Assisted

Although shipping has been powered by wind throughout history, the use of wind has been very limited during the last 100 years. Today, however, with the demands for decreased emissions and fossil-free propulsion and with higher fuel costs, various concepts of wind assistance in sailing have been tested. There is very little information on the outcome of the tests.

The use of rigid sails has been tested in various projects since the 1980s, but has not (in 2019) received widespread acceptance as yet. A 5-month test on a 7000 DWT bulk carrier pointed at a fuel saving of up to 30%, which is in agreement with model calculations for use in open sea. There are also “hybrid sail” concepts with combinations of soft and rigid sails.

Wind-assisted sailing using kite sails has also been tested and used. Calculations have shown that there is a theoretical possibility to save between 10% and 50% of the fuel, depending on wind speed, by using a kite on a 50,000 dwt tanker.

Flettner rotors are a way of creating additional thrust by wind. It is a high cylinder, standing vertically and rotating. It is driven by an electric motor. Tests on board have shown that it can deliver more thrust than the main engine under some conditions. Fuel savings of 7–10% have been recorded in on board tests. Theoretical calculations point at a potential fuel saving of up to 20%. Model calculations have shown that the use of Flettner rotors has the potential to provide cost-efficient propulsion, however, the payoff time is strongly dependent on the price of fuel (Tillig et al., 2018).

Nuclear

An alternative source of energy that can be used for propulsion of ships is the nuclear reactor. This has a long history for propulsion of military ships, mainly submarines, but also ice-breakers have been built. In 2016, around 166 naval reactors were in operation worldwide. The nuclear reactor has advantages in that it is emission-free during operation. It also needs refueling

only at very long intervals. The use of nuclear propulsion for merchant ships has been tested in three ships in the 1960s, in Germany, Japan, and the United States. The conclusion from the tests was that the cost was far too high for commercial application. The ships were rebuilt to conventional propulsion or decommissioned. Security, as well as the opinion from some states and ports against calls by nuclear powered commercial ships, constitutes the main limitations on use. One argument for this is that the fuel in these reactors is high enriched and can easily be used in nuclear weapons, which makes the ships a security issue (Schoyen and Steger-Jensen, 2017). In recent years, there have been some initiatives to take up commercial development again, and the regulatory framework has been updated by class societies. At present (March, 2019) there is a tender from China for building a 30,000 tons ice-breaker.

Fuel Cells

Fuel cells are used to convert chemical energy in a fuel into electrical energy and have been tested for use on board ships, especially for generating electricity for on board use. Dependent on the fuel cell technology different fuels can be used. Hydrogen is the most common but it is also possible to use LNG, methanol, and ammonia, for example.

Emissions to Water and Impacts

Oil Spills

Crude oil and various forms of petroleum products, for example, heavy fuel oil and diesel commonly end up in the natural environment. Calculations show that on average, 1,250,000 tons of oil annually end up in the marine environment from sea-based sources. Sources of oil to the marine environment that originate from shipping-based activities are accidents, groundings, operational discharges, and shipwrecks. These sources are responsible for approximately 34% of the total annual input. With better regulations, vessel design, and on-board safety installations accidents leading to large oil spills have decreased over time, however as shipping activities are increasing globally the volumes from operational discharges, for example, leaking-propeller shaft bearings, bilge water, and illegal discharges is increasing (Farrington, 2013).

Environmental Effects of Oil Spills

Oil spills can have two different effects in the aquatic environment, acute toxic or nonlethal effects. The volume of oil, type, location of the spill, time of the year, and weather conditions determines the effect of the spill in the environment. The normal biota at the site of the oil spill and the possibility of these organisms for recolonization also affects the total impact of oil spill.

Effects from single, large oil spills often have lethal effects in organisms. Through narcotic effects the organisms' cellular functions are highly degraded, as cell membranes lose the ability to uphold its normal homeostasis, which have lethal consequences. Organisms with feathers and fur are vulnerable to oil spills, especially seabirds. Even a small amount of oil on the feathering causes a loss of insulation capabilities, leading to hypothermia. Larger amounts cause seabirds to lose buoyancy and their ability for flight. Furthermore, effects from a large oil spill include the physically hindering of oxygen and sunlight transfer into the water caused by the slick. This leads to anoxia in shallow waters and lowered capability for photosynthesis, which entails reduced densities in marine plants and benthic fauna.

Small and continuous oil spills also cause negative effects in the marine environment, and is primarily caused by the most toxic part of oil, Polycyclic Aromatic Hydrocarbons (PAHs). This group of compounds exists in crude oil and petroleum products in various concentrations. PAHs have mutagenic, carcinogenic, dioxin-like, and endocrine-disrupting potential, consequences from exposure to PAHs can be considerable to a wide range of organisms. Exposure can, for example, result in the induction of cancer, decreased ecological and taxonomical community diversity, lowered fecundity and growth, and lowered tolerance to other stresses. Over time effects from a small, continuous oil spill can inflict equal negative effects on a community or population level as a single large oil spill (Lindgren et al., 2017).

Biofouling and Use of Hull Coatings

Hull coatings with antifouling properties is commonly used on ships to deter the accumulation of biological growth (biofouling), for example, microorganisms, algae, and animals on the hull and other surfaces of the ship immersed in seawater. Processes leading up to this growth begins immediately after a surface is lowered into the sea. In the final stage of this process, larvae of macrofoulers, such as barnacles, bryozoans, molluscs, and polychaetes will be under favorable conditions adhere (settle) to the surface and begin to grow. Finally, the surface will be covered with a thick layer of biological growth. The amount of biofouling on the immersed surface will depend on several factors, for example, water temperature, salinity, solar radiation, water depth, and interactions within the fouling community. If the fouling is left uncombated on the hull this will significantly increase the ship's hull roughness and drag, which will result in increased weight, reduced speed, and decreased maneuverability, effects which must be compensated for by increased fuel consumption. Another consequence is the possibility of alien species getting attached to the hull and thereby transferred to new areas.

Throughout history, seafarers have attempted to protect their hulls from fouling organisms. Indications exist that people used antifouling systems to protect ships even before 1000 B.C. As antifouling, in general some sort of toxic substance, biocide, is used to prevent organisms from attaching to the hull. In the 1960s Tri-Butyl-Tin (TBT) became the dominating biocide in antifouling paints and was so until 2008, when the substance was prohibited due to its negative effects also to nontarget organisms.

In modern hull coatings copper in various chemical compounds is used to deter fouling organisms. Copper is a metal that commonly occurs in the environment and living organisms need it in small amounts and use it for growth. However, copper is toxic to organisms at high concentrations and can occur in several different chemical states. The most toxic form of copper to living organisms is in its ionic form, Cu^{2+} . This easily passes through cell membranes and causes damage. The usage of copper in antifouling paints is often in the form of cuprous oxide, copper thiocyanate, or metallic copper, all leaking copper in ionic form. This leakage of copper ions then has an antifouling effect on for example barnacles, tube worms, and some species of algae. The leakage rate of copper from the coating is governed by several factors, for example, paint formula, age of the paint on the hull, the water temperature, and the pH. Due to both leisure boating and commercial shipping, high concentrations of dissolved copper are commonly found in shallow, near-coastal marine areas. Copper also adsorbs to particulate matter present in the water column, with the consequence of an accumulation in sediments. These shallow coastal areas are at the same time used as spawning, nursery, and feeding grounds by numerous marine organisms. The potential impact of copper on nontarget species is therefore substantial.

Ballast Water

Ballast water taken up to stabilize the ship when operating with less-cargo load, will include the marine organisms at the place of intake. This can be both larval stages of larger organisms as well as smaller planktonic animals, which will get transferred between ports in different geographic areas. When a new species is introduced in a sea area the consequence will be dependent on several factors. For example, if the introduced species is outcompeting native species by being fast in nutrient uptake and growth and if it is tolerant to physical factors like temperature and salinity, it might become invasive. The introduction can on the contrary be limited, for example due to predation by present species or by mismatch in reproduction requirements. The problem of invasive species transfer with ballast water was highlighted by researchers at the end of the 1990s and in 2004 the IMO Ballast Water Management Convention (BWMC) was adopted with the aim to limit the issue. In the BWMC the requirement of treatment to remove marine organisms from the water before discharge is described. The BWMC has been in force since September 2018.

Examples of invasive species transferred by shipping with great ecological impact and high mitigation costs is, for example, the *zebra mussel* that clog locks and water intakes, *Chinese mitten crab* that erode sediment banks and spread parasites, microalgae that can form toxic algal blooms and cholera bacteria that can start outbreaks.

Waste Generated on Board

Various kinds of waste are generated on board ships. This includes operational waste like oil/water mixes as well as waste generated by crew and passengers like sewage water and food waste. The tradition of dumping waste into the sea is old, and still in the 1960s there were recommendations of how to sink waste from leisure boats in a safe way. In general, there are IMO regulations prohibiting release to the sea, with some exceptions in MARPOL annex V. The exceptions include release of food waste outside special and arctic areas, if ground to smaller fractions at a certain distance (usually 12 nm) from the shore. The regulations put demands on the port reception facilities for waste.

Noise

Noise is also present underwater. Fish, invertebrates, and mammals are using sounds for communication, sometimes at frequencies that are similar to those generated by ship propellers and engines. Different effects can be the result of anthropogenic noise. First, permanent and temporary hearing loss can be a consequence. Then modifications in the amplitude and frequency that are needed to detect sound have been the negative result from the noise. Secondly, masking can occur. Then alien sounds cover a desired signal, rendering detection more difficult, which can hinder communication, mating calls, and the search for prey. Finally, behavioral changes in response to a sound, which can include the abandonment of an important activity, for example, feeding, nursing, or the use of an area, can be the response to a sound (Andre, 2018).

Particularly Sensitive Areas, Baltic Sea, Arctic, and Others

Some marine areas are classified by the IMO as Particularly Sensitive Sea Areas (PSSAs) for ecological, socioeconomic, or scientific reasons. These areas are considered as being in risk of damage from maritime activities. Actions like stricter environmental regulations (The Baltic Sea) or routing systems (The Galapagos Islands) are taken. There are currently 17 areas classified as PSSAs. The IMO MARPOL regulation does also include Special Areas with stricter discharge limits under its six Annexes for different pollutants.

Ships trading in the polar regions are since 2017 regulated under the IMO Polar Code. The Polar Code include safety and environmental provisions ranging from design rules to navigational advice like for example prohibitions on the release of oily mixtures and prevention of pollution from garbage and noxious liquid substances. Areas with stricter national regulation can be exemplified by Norway that targets zero emissions in the fjords, US-Alaska with strict wastewater treatment requirements and New Zealand and Australia with special biosafety regulations to avoid transfer of invasive species with hull fouling.

Sustainable Shipping in the Future

After a couple of decades with stricter regulations of emissions to sea and air, there are still more challenges to address to achieve an environmentally sustainable shipping sector. Shipping has a large challenge, which it shares with other transport and energy sectors, in becoming fossil-free in the coming decades. In addition, there is a need for a general decrease of emissions, and a “zero vision” for shipping emissions is discussed as a goal. Although regulations and technical improvements are making the environmental impact from shipping less detrimental to the environment, geographical areas and/or toxic chemicals are at risk of becoming new or increased problems in the future. Future shipping will most probably use many different technologies and fuels in order to strive toward the zero-emission vision.

Biographies

Karin Andersson is a professor emerita in Maritime Environmental Sciences at Chalmers University of Technology. Starting with M.Sc. in Chemical Engineering and a Ph.D. in Nuclear Chemistry, Karin's research is focusing on environmental and energy assessments of technical systems. In the last 10 years the main focus has been on the relation between shipping and the natural environment, providing decision support for industry, and policy makers.

Selma Brynolf, Ph.D., is a researcher at the Department of Mechanics and Maritime Sciences at Chalmers University of Technology. Selma's research is focused on assessing future fuels and propulsion technologies for transport with focus on shipping using tools such as life cycle assessment, multicriteria decision analysis and global energy system modeling.

Lena Granhag is an associate professor in Maritime Environmental Science at Chalmers University of Technology. Lena's background is in marine ecology and she works with questions related to the impact of shipping on the marine environment. Lena's main research interest is in ship hull biofouling, transfer of invasive species with shipping, and in finding sustainable solutions to these issues.

J. Fredrik Lindgren, Ph.D. is a senior adviser at the Swedish Agency for Marine and Water Management and researcher at the Department of Mechanics and Maritime Sciences at Chalmers University of Technology. Fredrik's research has been focused on ecotoxicological effects of the shipping industry, for example, operational oil spills, biocides from antifouling technologies, and dumped-chemical warfare agents.

Introduction

International shipping is currently at a crossroads. The decision of the 72nd session of the Marine Environment Protection Committee (MEPC 72) of the International Maritime Organization (IMO) in April 2018 to achieve by 2050 a reduction of at least 50% in maritime greenhouse gas (GHG) emissions vis-à-vis 2008 levels epitomizes the last among a series of recent developments as regards sustainable shipping. It also sets the scene on what may happen in the future. The so-called Initial IMO Strategy (IMO, 2018) is in the form of Resolution MEPC.304(72), and includes, among others, the following elements: (1) the vision, (2) the levels of ambition, (3) the guiding principles, (4) a list of short-term, medium-term, and long-term candidate measures with a time line, and (5) miscellaneous other elements, such as follow-up actions and others.

Against this background, the purpose of this paper is to present some basics as regards the energy efficiency of ships, including related regulatory activity at the IMO and elsewhere. This paper mainly draws from prior work by this author and his colleagues.

Before we proceed, a clarification is in order, and this concerns the definition of the term “energy efficiency.” In economics, efficiency typically means optimal allocation of resources to achieve a certain (multi-objective) goal. A solution is called efficient if it is impossible to improve one of the objectives without deteriorating another objective. Such a solution is also called Pareto-optimal. In that sense, the term “efficient” has a binary meaning, which means that a solution is either efficient or not efficient, and there is no sense of saying that a solution is more efficient than another solution.

In transportation, including shipping, “energy efficiency” is not binary, but can be measured. Energy efficiency is typically defined as the ratio of the amount of energy required to perform a certain amount of transport work, appropriately defined, divided by that transport work. In that sense, a solution can be said to be more energy efficient than another solution if it achieves a lower such ratio, that is, uses less energy to perform the same transport work. In shipping, energy efficiency is often associated with various indices, such as the Energy Efficiency Design Index (EEDI) or the Energy Efficiency Operational Indicator (EEOI), among others (definitions will follow).

For a specific type of fuel, since reducing the energy required to propel a ship is tantamount to reducing the amount of fuel consumed and since the latter is proportional to GHG emissions produced, achieving energy efficiency in shipping typically means reducing GHG emissions. In that sense, we shall not restrict ourselves to discussing EEDI and EEOI, but will also cover other measures to reduce GHG emissions, such as market-based measures (MBMs), and comment on the Initial IMO Strategy. Reducing GHG emissions can also be achieved through alternative (low carbon or zero carbon) fuels. For instance, nuclear propulsion will yield zero GHG emissions. However, in this paper we shall focus on instruments that can reduce GHG emissions assuming a specific carbon footprint for the fuel used. For a more detailed discussion of the issues that pertain to the decarbonization of maritime transport, see Psaraftis (2018).

The rest of this paper is organized as follows: section “The Energy Efficiency Design Index (EEDI)” introduces EEDI and also talks about EEOI. Section “The MBM Track” discusses MBMs. Finally, section “The Way Ahead” comments on the way ahead, including the Initial IMO Strategy.

The Energy Efficiency Design Index (EEDI)

The so-called EEDI, adopted by the IMO in 2011 as an amendment of MARPOL Annex VI, is thus far the most important (and in fact thus far the only mandatory) regulatory instrument for maritime GHG emissions reduction. EEDI basically aims to induce changes at the technological/design level that would bring about GHG reduction in the world fleet. Technological measures to reduce GHGs include optimized hulls, more efficient engines and propellers, and a variety of possible solutions such as wind-assisted propulsion, air lubrication, waste heat recovery, and others.

For a specific ship of 400 GRT and above, and built as of January 1, 2013, its EEDI is computed by the following formula (IMO, 2012):

$$\frac{\left(\prod_{j=1}^n f_j \right) \left(\sum_{i=1}^{nME} P_{ME(i)} \cdot C_{FME(i)} \cdot SFC_{ME(i)} \right) + (P_{AE} \cdot C_{FAE} \cdot SFC_{AE*}) + \left(\left(\prod_{j=1}^n f_j \cdot \sum_{i=1}^{nPTI} P_{PTI(i)} - \sum_{i=1}^{neff} f_{eff(i)} \cdot P_{AEff(i)} \right) C_{FME} \cdot SFC_{AE} \right) - \left(\sum_{i=1}^{neff} f_{eff(i)} \cdot P_{eff(i)} \cdot C_{FME} \cdot SFC_{ME**} \right)}{f_i \cdot f_c \cdot Capacity \cdot f_w \cdot V_{ref}} \quad (1)$$

The numerator in Eq. (1) is the total CO₂ emissions produced by the ship and is a function of all power generated by the ship (main engine and auxiliaries). The denominator is a measure of transport work and is a product of the ship's capacity (usually deadweight) and its "reference speed," defined as the speed corresponding to 75% of maximum continuous rating (MCR), the maximum power of the ship's main engine. The units of EEDI are grams of CO₂ per ton mile.

The EEDI of a specific ship, also known as attained EEDI, as computed earlier, is to be compared with the so-called EEDI (reference line), which is only a function of ship type and DWT (deadweight) and is defined as follows:

$$EEDI(\text{reference line}) = aDWT^{-c} \quad (2)$$

In Eq. (2), a and c are known positive coefficients that have been determined by regression from the world fleet database, and have been finalized for each major ship type after a long debate within the IMO. For a given ship, the requirement for EEDI compliance is that the attained EEDI value should be equal to, or less than, the so-called *required EEDI* value. The required EEDI value is proportional to the value of EEDI (reference line), as defined in Eq. (2), and the requirement can be written as follows:

$$\text{Attained EEDI} \leq \text{Required EEDI} = (1 - X/100) aDWT^{-c} \quad (3)$$

where X is a reduction factor ranging from $X = 0\%$ for ships built from 2013 to 2015, $X = 10\%$ for ships built from 2016 to 2020, $X = 20\%$ for ships built from 2020 to 2025 and $X = 30\%$ for ships built from 2025 to 2030. The year of build is defined as the year the ship's keel is laid. The rationale for factor X is the wish of IMO policy-makers to see newer ships becoming more energy efficient in the future, the latter being defined as having a lower EEDI than ships of similar type and size built earlier. In that sense, IMO policy-makers assume that EEDI compliance is a proxy for achieving GHG emissions reductions. However, things are not that simple and it turns out that several factors sometimes make the earlier assumption hard to justify.

First of all, commercial ships do not necessarily trade at the speed corresponding to 75% of MCR, or at any other predetermined speed. Whoever pays for the fuel (owner or charterer) will select an appropriate speed, which is a function of basically two factors: fuel price and freight rate. High fuel prices and/or low freight rates will induce slower speeds and hence lower fuel consumption. Conversely, low fuel prices and/or high freight rates will induce ships to speed up. Slow steaming, a much prevalent practice these days, may involve speeds drastically lower than the 75% MCR speed, and the corresponding reduction in fuel consumption will be even higher.

Second, fuel consumption is very much a function of prevailing weather conditions, and ship A that has a lower EEDI than ship B under calm weather conditions may have a far poorer fuel consumption than ship B in actual weather conditions. The behavior in other than calm weather conditions cannot be captured by EEDI, as defined earlier. An IMO delegation reported that even identical sister ships built by the same yard in the same period as part of a series program have EEDIs varying between 8% and 10%, the sole reason being different entries for the design speed recorded in commercial fleet databases. Such information is reported by ship owners or other sources, and is not independently verified.

But by far the most important deficiency of EEDI is what we call the "horsepower limit" deficiency. In Eq. (1), the traditional assumption, which comes from marine hydrodynamics, is that the ship engine's MCR, which is in the numerator of Eq. (1), grows to the cube of speed, V^3 , where V is the reference speed that appears in the denominator of Eq. (1). This means that EEDI grows like V^2 . In Eq. (3), speed does not enter the formula at all. It is straightforward to check that this combination is tantamount to imposing an upper bound on speed, corresponding to 75% MCR, and this would translate to an upper bound on MCR itself. Thus, in the quest of EEDI compliance, one would run the risk to see the construction of underpowered ships, which would be less safe to navigate and which, in their attempt to go faster or just maintain speed in bad weather, would emit more CO₂. Perhaps more important, this might also shift the focus of action from designing the best possible hull forms, engines, or propellers, which is the intended aim of EEDI, to the easy solution: just reduce MCR, or equivalently, speed at the design level. This means that any totally inefficient design could be made acceptable with the easy way out: a reduction in horsepower, or design speed. The existence of the earlier easy way out can hardly serve as an incentive for more efficient future ship designs.

The horsepower deficiency has been recognized at the IMO. Since 2011, a serious discussion has ensued, both within MEPC and MSC (IMO's Maritime Safety Committee), on how to reconcile EEDI compliance with the minimum safe power requirement. But the approach for such a reconciliation does not involve modifying the EEDI formulation. Recent documents submitted to the IMO suggest that an impasse cannot be ruled out. The impasse revolves around the dilemma between (1) seriously downgrading the requirements for ships so as to be able to safely navigate in adverse weather conditions, and (2) admitting that the whole EEDI formulation needs to be radically modified. The latter is already the case for Ro-Ro vessels. For these, the EEDI formulation is more complex, as some coefficients in the EEDI formula are not constant. The EEDI for this type of vessel was thus reconsidered by the IMO, as some industry stakeholders reported problems with the current formulation. In a recent study on CO₂ reduction targets and

related pathways (Smith et al., 2016) it was shown, among other things, that the existence of EEDI versus a scenario in which there is no EEDI as we move to 2050 amounts to a GHG emissions difference of about 3%.

EEDI being only a *design* index, its operational equivalent is the so-called EEOI, which is a *voluntary* index with a formula very similar to that of EEDI but, instead of DWT in the denominator, the actual amount of cargo carried is used. Also, total CO₂ emitted at the actual voyage speed (and not at 75% MCR) is estimated.

It turns out that there are several problems with EEOI as well, rendering it an unreliable indicator of operational efficiency. First, the effect of bad weather where a ship increases fuel consumption to keep a certain speed penalizes the EEOI value. In addition, a voyage with less than maximum cargo, or with zero cargo (on ballast), heavily worsens the EEOI value. Also, bad weather and ballast voyages are mostly out of the control of the operator and their effect on EEOI may be much larger than any best practices applied by the ship owner (e.g., course optimization, frequent hull and propeller cleaning, etc.) An energy efficient ship with the most prudent operator may have a good EEOI one year and a bad EEOI next year, thanks to the whims of nature and the markets.

Based on all of the aforementioned, the concept of EEDI (and by extension the EEOI), which is at this point in time the only mandatory instrument to reduce GHG emissions from ships, even though formulated and implemented with the noblest of intentions, suffers from some basic deficiencies. These will have to be resolved if one is to see a credible dent in GHG emissions in the future. However, how or if these deficiencies will be resolved seems pretty much open at this point in time. For a discussion of EEDI/EEOI including associated problems see Polakis et al. (2019) and for an alternative EEDI formulation taking into account weather conditions see Lindstad et al. (2019).

The MBM Track

The second most important instrument that the IMO has considered in order to curb GHG emissions has been the class of MBMs. By and large, and following the “compartmentalization” process that is prevalent in many of these discussions at the IMO and other fora, the MBM track has run in parallel to (and has been independent of) the EEDI track, even though there have been cross-linkages between the two, as some MBM proposals embedded EEDI into their formulation.

MBMs are instruments that apply the “polluter pays” principle and internalize the external costs of GHG emissions. In the short run an MBM (for instance, a bunker levy) can induce speed reduction and other logistical adjustments and in the long run it can incentivize technological advances (such as better hulls, engines, propellers and other technologies, and/or low carbon fuels). In both cases, GHG emissions would be reduced.

In 2010, an IMO Expert Group, appointed by the IMO Secretary General, and chaired by none other than the (then) Chairman of the MEPC, was tasked to evaluate as many as 11 separate MBM proposals, submitted by various member states and other organizations. These included a levy scheme, several separate Emissions Trading Systems (ETS), and various other proposals. All MBM proposals described schemes that would target GHG reductions through either in-sector emissions reductions from shipping or out-of-sector emissions reductions through the collection of funds and the spending of such funds to reduce emissions outside the maritime sector (for instance, building a wind farm in New Zealand or a solar farm in Indonesia). By making shipowners pay for their ships’ CO₂ emissions, an MBM is an instrument that can implement the “polluter pays” principle. In that sense, it may help internalize the external costs of these emissions. The IMO formulated a list of criteria for the evaluation of the MBM proposals, including environmental effectiveness, practical feasibility, administrative burden, compatibility with existing legal frameworks, and others.

The MBM Expert Group met on several sessions and produced a 300-page report with a detailed analysis of the 11 MBM proposals, including a discussion of alternative scenarios as regards fuel prices, projected emissions growth, and other parameters (IMO, 2010). The group’s modeling effort, which also involved the work of external consultants, was to develop and apply a model to make quantitative estimates of emissions reductions, revenues generated, costs, and other attributes of each MBM proposal. The group’s report contained no recommendation on any specific MBM proposal that could be chosen, and did not even contain a short list of MBMs, keeping all of them on the table. In fact, discussion on MBMs at the IMO level after 2010 was not very productive. The period to July 2011 focused on the adoption of EEDI, and not much was done on MBMs. The period immediately after the adoption of EEDI focused on practical matters involving its implementation and again there was little discussion on MBMs. A proposal by Greece in 2012 (who had submitted no MBM proposal of its own) for the IMO to decide on a short list of MBMs (essentially a bunker levy and ETS) was rejected. All MBMs continued to be on the table, except one that was withdrawn.

In addition to the almost complete lack of consensus among the MBM proposers (except for those promoting ETS who had a common position), the same group of developing countries (China, India, Brazil, Saudi Arabia, etc.) were as much against any MBM as they were against EEDI, particularly after they lost the EEDI vote in 2011. Their main objection was mainly on the grounds that MBMs were not compatible with the principle of *Common But Differentiated Responsibilities and Respective Capabilities (CBDR-RC)* (Stone, 2004). Then in May 2013, the MEPC decided to suspend discussions on MBMs. This was accompanied by a channeling of the discussion toward the subject of monitoring, reporting and verification (MRV) of CO₂ emissions. Today, some 6 years later, the MBM discussion at the IMO remains suspended, with no visible sign of reappearance any time soon.

A later twist in the MBM saga came with the February 2017 vote of the European Parliament (EP) to include shipping into the EU ETS as of 2023, in case no global agreement is reached by 2021. As mentioned earlier, this caused serious concern among industry stakeholders that such a *regional* MBM would create serious distortions, not to mention that it might not necessarily reduce maritime CO₂ emissions. In November 2017, and after some negotiations between the EP and the EU Council of Ministers, it was agreed to

align the EU with the IMO process, and essentially refrain from taking action on ETS before seeing what the IMO intends to do on GHGs. Industry circles, concerned with the effects of an early EU ETS, welcomed this development. However, the European Commission will closely monitor the IMO process, starting from what is agreed on the initial strategy in 2018 and all the way to 2023. Whether or not this latest agreement at the EU level might put some pressure on the IMO to resume the suspended discussion on MBMs and adopt a global MBM before the EU moves on ETS is unclear at this time. And even though the ETS looks like the default scenario for the EU if progress at the IMO is not deemed satisfactory, precisely what action the EU will take and when that action will be taken is equally unclear.

In April 2018, the IMO/MEPC reached the landmark decision to adopt an initial strategy for GHG reductions that sets (among other things) a target of GHG reductions of at least 50% by 2050, vis-à-vis 2008 levels (IMO, 2018). A broad list of potential measures has also been proposed, broken down as short-term (finalized and agreed to up to 2023), medium-term (2023–30), and long-term (2030 and beyond). MBMs are included in the set of *medium-term* measures, but only obliquely. To quote from the decision text, “new, innovative emission reduction mechanism(s), possibly including Market Based Measures (MBMs), to incentivize GHG reduction.” No measures have been specified to be adopted until 2023 at the earliest, the year when the strategy is supposed to be finalized. Other than the earlier wording, and as this paper was being finalized, there is nothing in the IMO process that would reopen the MBM discussion anytime soon.

How can MBMs help with the recently adopted ambitious IMO GHG reduction targets? Irrespective of the fact that MBMs seem not to be up for discussion in the foreseeable future, one idea that might be worth considering would be to impose a significant bunker levy on a global level. By significant we mean not 10 or 20 USD per ton of oil, as is being occasionally contemplated by industry, but at least one order of magnitude higher. This would induce both technological changes in the long run and logistical measures in the short run. In the long run, it would lead to changes in the global fleet toward vessels and technologies that are more energy efficient, more economically viable and less dependent on fossil fuels than those today.

How much CO₂ can be reduced by a substantial global bunker levy? Devanney (2010) estimated that with a base BFO price of USD 465/ton, a USD 50/ton bunker levy would achieve a 6% reduction in total Very Large Crude Carrier (VLCC) emissions over their life cycle and that for a USD 150/ton levy the reduction would be 11.5%. Some estimates of CO₂ reductions for tankers (Gkonis and Psaraftis, 2012) and handymax bulk carriers (Kapetanidis et al., 2014), and for several bunker levy scenarios, were also made. These estimates showed CO₂ reductions of more than 50% for a single VLCC if fuel price rises from 400 to 1000 USD/ton. However, the long-term fleet-level impacts of substantial levies are by and large unknown. For a discussion of the MBM concept and of the various MBMs proposed to the IMO, see Psaraftis (2012) and Psaraftis and Woodall (2019).

The Way Ahead

The reception of the April 2018 Initial IMO Strategy was almost universally laudatory. Not only industry associations but also the European Commission, the Organisation of Economic Cooperation and Development, and several nongovernmental organizations hailed the result as an important first step toward the eventual full decarbonization of shipping. There were very few expressions of dissatisfaction. At the same time, the following can be said.

First, the two stated principles that are centrally included in the Initial IMO Strategy, that is, (1) nondiscrimination/no more favorable treatment and (2) CBDR-RC, are in direct conflict with one another. The latter principle was included so as to please the group of developing countries who stood and continue to stand firmly behind CBDR-RC. Some would suggest, however, that one will need to find a way to circumvent or even eliminate the CBDR-RC principle altogether if any serious progress is to be made.

Second, that GHG emissions are to reach a peak as soon as possible is a laudable goal, but raises the obligatory question, how soon. According to the third IMO GHG study (IMO et al., 2014), in 2008, the baseline year as far as comparison to target values is concerned, CO₂ emissions of international shipping were estimated at 920.9 million tons, and declined to 795.9 million tons in 2012, even though they reached 849.5 million tons in 2011. As of yet, and pending the fourth IMO GHG study (which will be commissioned in 2019 and finalized in 2020), there is no consensus on GHG emissions figures after 2012. And even the earlier figures are based on the “bottom-up” (activity-based) method, whereas emissions figures based on the “top-down” (fuel sales-based) method are significantly lower (624.9 million tons in 2008 vs. 648.9 million tons in 2011—there was no top-down estimate for 2012). There should certainly be consensus on which method is used (“bottom-up” numbers are 30%–50% higher than “top down”), plus consensus on when the GHG peak is expected to occur. Barring any major world trade slowdown, it seems self-evident that for any GHG peak to be reached some measures will have to be implemented—no peak will happen by itself.

“Speed reduction” (or mandatory speed limits) is included as a potential short-term measure, even though the term “speed optimization” was added so as to make the measure more palatable to some South American countries who are concerned about their agricultural exports to Asia. At first glance, speed limits may seem like a reasonable measure. However, they are plagued by various deficiencies and would create distortions and other problems. For a comparison between GHG emissions reductions that can be achieved by a bunker levy and those that can be achieved by speed limits, see Psaraftis (2019).

Perhaps more important, there is not yet a sense of priority among the wide array of candidate measures, all of which are on the table. Indicative is the fact that, after a fierce debate at MEPC 73 (October 2018), the updated plan all the way to MEPC 80 in 2023 changed the wording from “prioritization” to “consideration” of the candidate proposals. Is this really the message that one would like to convey as a clear indication that one means business on the subject of energy efficiency of ships?

For a more thorough discussion on what may lie ahead as regards sustainable shipping and specifically the quest to improve the energy efficiency of ships, see [Psaraftis and Zachariadis \(2019\)](#).

Introduction

Ports are an eclectic mix of public and private activities that are geographically situated on navigable waterways, generally for the purpose of moving goods in domestic or international trade. Ports may also move people, as cruise ports, to tourist destinations around the globe. This section of the encyclopedia provides an overview of the types of cargo-handling in ports, by commodity and by governance structure. Fundamental aspects of the role played by port authorities are explained in the sections devoted to port planning and port marketing. Current perspectives related to port labor, particularly in the wake of automation of many traditional port labor functions is provided, despite the fact that the hiring and supervision of port labor may not be the obligation of the port authority, particularly for ports that are landlords. Today ports face a myriad of challenges. Highlighted here are ones of primary importance—port security, environmental challenges, and climate change and the consequence of sea level rise.

Seaport Typology and Governance

There are several ways to characterize ports: by cargo, like container ports; by function, like feeder or hub; or by governance model, like private or government-owned.

Characterized by cargo type, seaports may be single purpose or multipurpose ports, and so may serve a varying combination of market segments depending on their business opportunities. Ports are often called by their predominant cargo type, such as a container port, or bulk port but it is not uncommon to find that a so-called container port may also handle other cargo types. Similarly, some smaller government-owned ports, typically non-container ports, are often referred to as “niche” ports. The market segment of niche ports tends to rely on traditional, non-containerized cargoes, such as automobiles or seasonal fruit moved as break-bulk cargo.

Generally, there are no clear-cut patterns to categorize port market segments by governance type. Successful ports tend to be opportunistic and strive to accommodate as many different types of cargo and customers as they have facilities for. As such, larger ports managed by a governmental authority tend to be multipurpose ports. Fully private ports tend to be single purpose ports, often a single terminal that specialize in one particular cargo type such as liquid bulk (crude oil, petroleum products, molasses), lumber, or dry bulk cargoes like coal or alumina. For every generality about port typology, one can find exceptions due to the complexity of port ownership, management, and operational control and the global variations in the market.

Within a particular region, ports may also be characterized by the function they play in relationship to other ports or trading patterns. Feeder ports serve to collect and transport goods, such as containers, from their local hinterland to a larger hub port for international shipment. This is common in a situation where not all the ports in a particular region have the market strength or facilities to handle larger ships, but rather serve to ferry goods to a larger hub port or gateway that has sufficient facilities and capacity for larger ships moving in the global trading lanes. These feeder ports can be part of a cargo relay system or one of the “spokes” in a “hub and spoke” system. For example, some Japanese ports serve as feeder ports to Busan, Korea. Similarly, transshipment ports (e.g., Shanghai), where cargoes are moved from one vessel to another, can also serve as collecting points for a hub port. A hub port might also be characterized as a “gateway” port, meaning it has extensive rail, highway, or

waterway access to serve a deep hinterland (e.g., Los Angeles). Governments under international regulatory regimes remain responsible for port security and port state control, but may have agreements for alternative compliance regimes to deal with these responsibilities.

Ports are often characterized by governance model because it is possible to identify a reasonable number of discrete patterns found among governance in our world ports (Baltazar and Brooks, 2007). Because seaport operations typically involve multiple actors charged with the management, regulation and/or operation of services that utilize a navigable waterway, port governance is a significant reflection of the tension between regulators, local and national governments, and the private sector. There are five typologies of port ownership, management and operations, which are useful in understanding the key relationships that direct the ability of the port to serve the various user types:

1. Central government-owned with central government management and operations (Examples: National Harbors Board ports in Canada pre-1982, Spain pre-1992, Italy pre-1994, Greece pre-1999);
2. Regional or local government-owned with management by the regional or local government body. Operations may be a combination of public terminals operated by the government (operating port) or with some or all facilities operated by the private sector via a concession or lease (Examples: Most US ports);
3. Government-owned (national, regional, or municipal) but managed by a corporatized entity (Examples: Melbourne in Australia pre-2016; Sydney in Australia pre-2013; Rotterdam in Europe);
4. Government-owned but managed by a private sector entity via a concession or lease arrangement with a terminal operator, or owned and managed via a public-private partnership agreement (Examples: Many ports in developing countries, Melbourne post-2016; Sydney post-2013); and
5. Fully privately owned, managed and operated (Examples: Many UK ports)

While private ports exist in most countries, few countries have contemplated full privatization of the port sector. Outside of the United Kingdom, most privately held ports serve single cargo facilities—mines, refineries, power plants, and the like. Multi-purpose ports are usually developed with public funds. The dominant model of port governance in the second decade of this century is the landlord model. A publicly-owned port authority acts as the landlord and private companies carry out port operations on behalf of those government owners, usually through a lease or concession contractual arrangement.

Port reform efforts by governments have often focused on trying to extract lease payments for positive cash flows to government or long-term lump sum concessions for government debt reduction. While the principles of good governance would encourage that there be a separation of regulator versus operator functions, this does not always happen. Across the globe, there are many models of port governance, and most research concludes that there are few best practice approaches and no one right way for governments to establish the governance structure and port policies for the ports in the country (Brooks, et al., 2017; Brooks and Pallis, 2012; World Bank, 2007).

Port Business Models

Seaports generate revenues through fees for services offered to port users. Seaports typically have published tariffs, which indicate their rates and charges for port users. Those fees generally consist of wharfage, the fee associated with moving a particular cargo across a wharf for loading or offloading a ship; dockage or berthage, the fee assessed against a vessel for berthing or making fast against a wharf, pier, bulkhead or other structure; demurrage, the fees for storing cargo left on the wharf; and, pilotage, the fees for the service of providing a harbor pilot to guide movement of a ship into, out of, or within a port. Fees can also be assessed by the port authority for the right to anchor a vessel within the jurisdiction of the port.

Landlord ports will enter into short- or long-term agreements (leases or concessions) where real estate is leased to a private company, like a stevedoring company, that will operate the facility or terminal. In some cases, the landlord port will build the terminal for its customer and lease the land with improvements. In other cases, the tenant will construct some of all of the improvements. Port customers that have leased a facility may have a compensation structure that differs from the published rates and charges. Seaports strive to generate sufficient revenue through compensation paid by its customer(s) to allow reinvestment for improving harbor facilities. Historically, a typical business model for a port authority was to lease a terminal to an ocean carrier or stevedore for a long-term, such as 20–30 years, with a guaranteed annual minimum payment to the port authority. This minimum was typically set to allow the port authority to realize a return on its investment, as well as allow for reinvestment in modernizing the terminal facilities over time.

The port's investment in the capital expense of terminal construction may be financed by issuing bonds, using taxing authority or via a public-private partnership (P3) with an investor or its customer.

Structural changes in the ocean shipping industry, including the consolidation of the seaport's multiple customer base into fewer but larger ocean carrier alliances, have challenged traditional port business models. Ocean carriers may have eliminated their commitment to call at specific terminals for long periods of time, jeopardizing a port's reliance on the long-term commitment of cargo. Investment in new terminals or terminal expansion projects are riskier if ports cannot guarantee that enough cargo will use the terminal long enough for the port authority to recover its investment. Thus, ports have developed various alternative financing strategies to their traditional approaches. From the port's perspective, risk reduction means strategies that transfer or share the risk. These strategies range from a private concession/equity approach working with private equity funds that focus on infrastructure

investments, to P3s that continue the port's traditional role as the landowner and landlord role but with private equity making the infrastructure investment. Having a commitment by ocean carriers to move cargo through the terminal is vital to making a P3 economically viable.

Port Planning

Port planning is a key activity of port managers. Capital investments and growth for new business should be built on measuring port performance and productivity numbers. The challenge here is that there is no consensus on how a port's efficiency or productivity should be measured. Without understanding the existing productivity of a port, it is difficult to plan for future infrastructure needs. In less developed countries, for example, containers may be lifted from a ship's deck by a mobile crane, using a crew of several workers and managing one container every several minutes, while in a developed country port, there may be multiple shore cranes working the ship, each crane able to offload one or two containers with efficiencies that have been recorded as high as less than one minute per lift, and using one operator per crane.

There are multiple plans produced by a port authority. These may include:

1. Comprehensive, master, or long-range plans, which detail the spatial organization of the port, often serving as the fundamental guide to port land use policies and the designation of specific uses for land and water areas. These plans require periodic updating, generally after five years.
2. Facility or project plans, which focus on the engineering, economics, and environmental impacts of the proposed development project. The outcome of this process should be a development plan sufficient to pursue project funding or financing.
3. Capital Improvement Plans, which prioritize multiple projects and are tied to the port's budgetary process. Because the development of a port project may take many years, ports typically have 5- or 10-year capital improvement plans.
4. Risk management plans, which dictate the policies for regulating the siting of port facilities that handle hazardous cargoes. A fundamental tenet of port planning is co-location and segregation; these plans co-locate similar land uses as much as feasible, and segregate incompatible land uses such as public use areas and hazardous cargo facilities.
5. Strategic plans, which include an analysis of the forces affecting the port's internal and external environment and those that will shape the port in the future. A plan can be both outward-facing—that is dealing with the port's relationship with its customers and stakeholders, and inward-facing—that is dealing with its own governance, internal operations, and employees. The strategic plan identifies the port's mission, vision and values. The desired outcome of a strategic planning process should yield an understanding of a port's market and competitive position in context with those ports against which it competes. These plans are typically updated annually or every few years.

A comprehensive master plan should facilitate project decision-making based on longer-term trends in trade growth and an analysis of the port's particular market. The plan should be based on an econometric forecast of trade volumes, examining long-range forecasts of GDP, bilateral trade movements and potential disruptors to established trading patterns, along with a determination of the throughput capacity of the existing port facilities to identify gaps that trigger new facility development. Examples of disruptors to trading patterns can include the expansion of the Panama Canal in 2016, climate change and the potential of year-round shipping through the Arctic. Research on Asian ports has found that natural disasters and labor strikes are the two most common disruptors that ports must prepare to address in the master plan (Lam and Su, 2015).

Another important feature of a comprehensive port plan can be the port-city interface, particularly for urban ports where there is a desire to enhance the bond or create buffers between the city and the port. Here, factors like preserving scenic views of the water and ensuring consistency between urban mobility plans and port connections could be important. Where a port has developed historically in the core of an urban center, planning for new facilities can be constrained by limited land area, creating a need to examine efficiency improvements within the port's existing jurisdiction as the strategy for growth or examining growth opportunities in the port hinterlands. A best practice in port planning is conducting outreach with stakeholders, including not only port users and regulators, but also members of the public and residents of surrounding communities.

With the unprecedented pace of changes in maritime-related technology however, port planning should be viewed as a continuous process and not an end result. This is particularly true in the areas of port strategic planning and facility and project planning.

Marketing and Competition Between Ports

While some bulk ports serve captive customers (mines, refineries, and the like), most ports must compete for the cargo they handle. A seaport is only as competitive as the origin-destination total supply chain (for the products it handles). A cargo owner seldom uses only one port, as mitigating route risk (due to disruption by natural forces, labor unrest, or terrorist actions) encourages some splitting of the business across more than one route (and port); a slower but more reliable route will share traffic with a faster but less reliable one. The intention of route diversification is to minimize the probability of an inventory stock-out at

destination. While this may result in higher inventory carrying costs in transit for the cargo owner, such a strategy may more than offset the cost of the additional buffer stock or the consequential losses arising from a production shutdown or a retail stock-out for the cargo owner.

Other factors affecting port competitiveness include the quality of the hinterland connections, and the origin-destination transit time. In North America, rail connections and efficiency can pit a port on one coast like Vancouver, Canada against another port, like New York, on a different coast. Ocean carrier reliability concerns spill over onto port competitiveness, just as port capacity concerns, strikes, and lockouts spill over onto a cargo interest's choice of ocean carrier. Transit time variability is examined closely as shippers seek performance data not just on ocean carrier arrival reliability but also on container yard dwell time, and trucking company delivery performance. Total logistics costs drive the route decision for those companies seeking greater control of their operations, better customer experience and shareholder value creation.

There is divided opinion on the best way to market a port. Some ports see their role as being focused on serving the ocean carrier as customer, delivering promised port efficiency in cargo handling. Others, particularly those without a "must call" population base, are more focused on the target market of cargo owners, convincing those importers and exporters that the port can meet their needs, with marketing to the shipping line secondary. Still others are port community-focused, knowing that if the region is not served with good transportation access to warehouses, and efficient hinterland connections, the social license they need to continue to serve port customers will evaporate. Most port managers today focus on a multi-pronged marketing approach, a combination of these three. There remain, however, ports whose management continues to see their primary "customer" as the government they act on behalf of, and their decision-making has a political focus. Many ports undertake economic impact studies, identifying the jobs created and financial benefits to a particular region, to assist with local political efforts.

Labor

Port labor is often a contentious issue in the management and operations of ports. There are multiple perspectives about what is the correct number of dock workers.

First, there is the view of the day-to-day terminal operator, whose efficiency may be measured in terms of tonnage or containers moved per employee hour, and therefore is seeking to improve the level of productivity of each employee and minimize the number of employees for the expected cargo volume. This may trigger plans by the operator to automate many port processes, substituting capital investment in high-technology equipment for port labor costs.

Second is the view of those employees. In many parts of the world, dock labor is highly unionized and has been effective in gaining high wages for port workers. In such cases, unions are reluctant to concede hard-won labor contract gains, even under the threat of automation of terminal activities.

Third is the view of government. In many countries, particularly those in the developing world, ports are seen as important employers in the community, and the government is keen to increase employment numbers rather than focus on efficiency, putting political pressure on ports where governance structures allow.

Efforts to automate ports may therefore come up against either governments or unions or both, while in high-labor-cost countries, decisions to automate can be dependent on the availability of capital for that investment or driven by the share labor costs represent in the port or terminal's total budget.

Critical Issues for Ports

Port Security

The modern port security regime is a product of global security initiatives galvanized by the terrorist attacks on the United States of 11 September 2001. Multilateral regulators implemented new security requirements under the auspices of the International Maritime Organization, which in 2002 developed the *International Ship and Port Facility Security Code (ISPS Code)* and added it as an amendment to the *Safety of Life at Sea (SOLAS) Convention, 1974*. As most countries have adopted SOLAS, the ISPS Code effected a global common approach to port security as the Code sets forth mandatory security requirements to be taken by governments, ports, shipping companies, and terminal operators. These requirements came into force on 1 July 2004. Each country's national authority certifies those ports that meet the Code.

The ISPS Code defines maritime security (MARSEC) levels. The local government sets the security level and informs the port and ships prior to entering the port, or when berthed in the port. Each of the security levels under the ISPS code describe the current scenario related to the security threat to the country and its coastal region, including the ships visiting.

- Level 1 is the normal level that the ship or port facility maintains on a daily basis, and is a minimum of appropriate security on a 24 hour a day, seven days a week basis.
- Level 2 is a heightened level for a time period during a security risk that has become visible to security personnel.
- Level 3 is an additional level of security with measures for an incident that is forthcoming or has already occurred.

Each MARSEC level has specific actions expected of the port and a vessel's personnel to maintain port security.

Environmental and Sustainability Challenges Facing Ports

Most ports face a myriad of environmental and sustainability concerns, including air pollution from ships, access road congestion, and the resulting air pollution in the vicinity of the port, water pollution, ballast water that carries invasive species, local habitat protection, and the disposal of dredged materials. Globally, ports are working to reduce their environmental impact in a multitude of ways ranging from reducing water and air pollution, reducing traffic congestion, minimizing the production of greenhouse gases, and shifting to cleaner energy sources. By virtue of the port being a node where multiple types of transportation sources come together, ships, trains, trucks, and terminal equipment, ports have served as laboratories for the testing of new types of energy efficient and green technologies. In many cases, the increase in environmental consciousness on the part of ports can be attributed to the environmental activism among near-port communities. While some ports have been forced into greener operations by regulators, all ports have realized the benefits of sharing best practices and adapting them to their own port's environment.

Since 1996, the European Sea Ports Organization has surveyed its members to identify the top 10 environmental issues facing their member ports. Not surprisingly, in 2018 air quality is number one and has been since at least 2013. Many regional and national port organizations have committees or areas of specialization devoted to the environment. Many of these port associations have created environmental or green port awards to encourage ports to share their best practices (for example, American Association of Port Authorities Environmental Awards, European Sea Ports Organization's Environmental Award, Asia Pacific Port Services Network Green Ports Award). Many global ports have become members of the World Ports Sustainability Program (WPSP), part of the International Association of Port Authorities. Here, individual ports will lead specific focus areas, encouraging information sharing and dialogue. One international program developed by the predecessor to WPSP, the World Port Climate Initiative, is the Environmental Ship Index, an incentive program ports can join to attract the cleanest ships to their harbor, similar to the Green Award program established by the Port of Rotterdam and the Dutch Ministry of Transport and Water Management to initiate market incentives that promote green shipping. The Clean Air Action Program developed by the Port of Los Angeles and Long Beach includes a technology advancement program to encourage "proof of concept" for port related technologies to reduce air emissions.

Climate Change and Adaptation to Sea Level Rise

Climate change and sea level rise are global challenges that necessitate actions at the global and local level for seaports. Global actions in the maritime realm fall within the purview of the International Maritime Organization, which is currently focused on reducing the greenhouse gas emissions of vessels. Ports sit on the frontlines of global climate change due to their coastal location and are thus positioned to take necessary actions with their region as part of their ongoing development functions. Mitigating climate change through the reduction of greenhouse gases is now a mainstream activity of ports. Most ports are focusing on "hard" engineering measures as their main response to address sea level rise (UNCTAD, 2018). Thus, many ports already address sea level rise in their design of new piers and infrastructure (Ng et al., 2015). Landlord ports have additional challenges where they have leased their waterfront to port terminal operators under long-term concessions. It may be hard to incentivize a concession holder to take actions now to adapt to sea level rise when the length of their concession may only be 20 or 30 years. Many concessionaries view this as making investments that would benefit future concession holders. Yet, the ports that will become the most resilient to climate change in the future are the ones where climate change policy is considered in concession agreements.

Sea level rise is only one of multiple challenges ports face due to climate change. The melting permafrost that supports railroad tracks in northern Canada, the extreme temperatures experienced by dockworkers in Australia, the lower water levels of the North American Great Lakes and Gatun Lake in the Panama Canal are all examples illustrating the wide range of impacts on port infrastructure, operations, and worker health and safety. The challenge for all ports is to figure out how to proactively address climate adaptations today rather than waiting until they are forced to react in a crisis situation. Remarkably, the efforts of many ports to "green" their operations have had the unintended consequence of making the ports less resilient. Reducing the production of greenhouse gases by replacing the use of diesel-powered equipment with electrically powered equipment is one example where the vulnerability of the port may be increased in the case of a severe weather event involving the loss of electrical power.

Biographies

Dr. Mary R. Brooks is Professor Emerita at Dalhousie University, Halifax, Canada, and a founding editor of *Research in Transportation Business & Management*. In 2016–18, she served as Chair of the Marine Board of the US National Academies. Her research focuses on competition policy in liner shipping, port strategic management and short sea shipping. She has authored and published more than 25 books and technical reports, more than 25 book chapters, and more than 80 articles in peer-reviewed scholarly journals. In September 2018, she received the Onassis Prize in Shipping 2018, in recognition of 'her outstanding contribution to the study of shipping.'

Dr. Geraldine Knatz is Professor of the Practice of Policy and Engineering, a joint appointment between the University of Southern California School of Public Policy and School of Engineering. She served as the CEO of the Port of Los Angeles from 2006 to January 2014 and prior to that was Managing Director at the Port of Long Beach. She is past president of the American Association of Port Authorities and the International Association of Ports and Harbors, and founding Chairman of the World Port Climate Initiative. In 2014, Knatz was elected to the National Academy of Engineering in recognition of her international leadership in the

development of environmentally clean urban seaports. That same year she was honored with Containerization & Intermodal Institute's Lifetime Achievement Award.

Ports and Their Hinterlands: The Impact of Containerization

The concept of a port hinterland has changed dramatically over the years, following the evolution of maritime transport and the logistics industry. A hinterland represents the inland catchment area of a port, from where it produces the majority of its business. Indeed, the points of origin/destination of cargo flows, which passes through the port, are located in the hinterland. In summary, the traditional notion of a hinterland refers to the economic area influenced by the ports. It is rather complex to identify the boundaries of a hinterland's extent, as this largely depends on the different commodity flows and transport modes. Furthermore, a hinterland's size is constantly changing over time due to economic cycles, seasonality effects, technological transformations, evolutionary changes of carriers the strategies of multimodal transport operators, capacity constraints of infrastructure, modifications in transport policy, etc. Hence the concept of a port hinterland is very dynamic and a static approach, considering port hinterlands as being everlasting may be misleading (Olivier and Slack, 2006).

Academics began in-depth investigations into port–hinterland relationships in the 1960s, even though some pioneering studies date back even earlier. Formerly, the concept of a hinterland was mainly founded on zonal models, paying scarce attention to the relevance of inter-port inland competition. Then, the containerization process and intermodality broke this approach and pushed the integration of ports as nodes of global transport chains. Therefore the selection of gateways and corridors by carriers has been placed at the center of the debate, reshaping profoundly the concept of the hinterland (Ferrari et al., 2011).

Nowadays, a port hinterland is viewed as a broad logistics area strictly linked to global supply chains and international transport players. The shape of the hinterland is no longer considered a function of the physical distances involved and it seems to be affected by numerous discontinuities along its boundaries. Such discontinuities are provoked by inefficiencies across the logistics chain and also by the contextual competition of distant ports. Although some scholars still persist in considering distance as a driver for defining port hinterlands, most academics assert that the competition among the top players is not necessarily grounded on inland distance.

Hinterlands Become More Contestable

The emergence of global networks affected the relationship between the nodes of the supply chain and their market areas. In this perspective, it is possible to identify some key factors that have facilitated the growth of gateway ports with the characteristics to compete for contestable hinterlands. Academics have extensively studied the relationships between gateway seaports and the hinterland, focusing on the drivers, which have affected port catchment areas. In particular, containerization and intermodality represent two pivotal factors for the extension of port hinterlands and the strong intensification of interport competition.

The invention of maritime containers triggered a significant revolution in the transport industry. Containers have become the common transport unit, enabling maritime transport to stretch the business toward land and to build innovative door-to-door systems. In the second revolution, the development of intermodality, most closely associated with rail and barge transport, further enlarged the land penetration of maritime containers through the creation of landbridges (Muller, 1999). This revolution, together with the introduction of logistics corridors, has largely widened port hinterlands, leading to a paradigm shift from “captive to contestable” hinterlands. Moreover, the perception of port markets has passed from being monopolistic or oligopolistic to being competitive, opening new possibilities for further exploring and developing the business.

These changes have deeply affected the relationships among ports located in the same range (e.g., Rhine-Scheldt delta, Southern California, etc.) and also, to a certain extent, in opponent ranges (e.g., USWC vs USEC, Northern vs Southern range ports in Europe, etc.), producing a much fiercer on-shore competition for capturing cargo. As a result, the competition led to the “natural selection” of some gateways, which emerged as leaders for their operational reliability, maritime strategic location, as well as their effectiveness in inland penetration. Notably, these gateways represent nodes of global maritime networks and, thus, allow long-haul transport flows to reach broad continental areas and vice versa. It is widely demonstrated that containerization and intermodality have progressively eroded traditional hinterland paradigms. Indeed, the growing hinterland contestability has altered hinterland size, as well as its shape. Hinterlands also became characterized by more discontinuous physical boundaries, even in the immediate vicinity of the port. [Notteboom and Rodrigue \(2005\)](#) argued that this process may lead to the formation of “islands” in the distant hinterland, where the load center port in question achieves a comparative cost and service advantage with respect to their competitors. Hence traditional perspectives based on the concept of distance decay are unsuitable to face this new scenario. In this regard, as mentioned earlier, the effectiveness of inland connections and the relationship with inland terminals are fundamental for port competitiveness.

Ports are Inserted into Broader Supply Chains

The rise of corridors has influenced the relationship between gateway ports and their hinterland. These logistics infrastructures enable maritime gateways to enhance their penetration toward the hinterland and increase traffic volumes. In the past, the competitiveness of a container port was grounded on its standalone “physical” features (e.g., asset endowment, nautical accessibility, ship-to-shore performance, container dwell time, etc.). Nowadays, however, port selection is strongly conditioned by hinterland accessibility and, thus, by the quality of gateway port-hinterland connections. In this vein, physical attributes cannot be used as the only parameters for assessing the competitiveness of a port, since they no longer reflect the complexity of global supply chains. This has been provoked by globalization, the delocalization of production plants as well as the physical dispersion of manufacturing inputs over a broader geographic space. Multinational manufacturers, indeed, have introduced a more flexible multifirm organizational structure, based on the fragmentation of production and logistics activities throughout globally outstretched supply chains ([Olivier and Slack, 2006](#)).

In this perspective, ports became only a stage in the entire logistics equation, and their competitiveness is mostly shaped by the efficiency of logistics operations beyond port boundaries and, especially, by their inland connectivity and reliability. Therefore ports have been increasingly competing not as individual maritime nodes, basically responsible for loading and unloading cargo, but as crucial interfaces within different logistics chains. For this reason, ports are expected to shift their strategy to an overarching supply-chain approach aiming at meeting the requirements of both carriers and shippers. Consequently, this might also suggest in terms of governance mechanisms, the creation of an independent public body for coordinating the activities along the supply chain, including port operations and hinterland transportation. This is crucial for the proper functioning of the network, as the lack of integration among public bodies (e.g., port authority, municipality, region, central government, etc.) and private companies can generate institutional problems and serious bottlenecks.

Shaping Port Hinterlands: A Mix of Positive and Negative Forces

The earlier-mentioned arguments suggest that the capacity of a port for attracting cargo is strictly correlated to the degree of inland penetration. In this vein, port and hinterland appear as a unique interconnected entity and the competitiveness of this broad logistics area is determined by the mutual attractiveness of port and hinterland together, as well as their attitude toward collaborating with each other. In particular, the quality of hinterland connections heavily affects port competition; port attractiveness is increasingly dependent on overall network costs and performance. Hence port selection criteria strongly take into account the role of the port as a pivotal node within the global supply chain ([Ferrari et al., 2011](#)).

Hinterland contestability can be seen as the contextual intervention of positive and negative “forces” (standalone and external factors) across the overall transport chain. These “gravitational forces” attract ports and hinterlands to each other and generate traffic flows between them. Among these drivers, the extant literature suggests that the main important ones are: the effectiveness of port handling operations, the location of distriparks and inland terminals within and nearby the port domain, the presence of an international business environment, a strong local cargo base (calling for transshipment operations as well as additional gateway cargo for long inland distances), fast vessel turnaround times, short container dwell times, efficient rail, road and barge networks, and effective port governance. These positive forces extend port hinterland coverage and foster its capacity to compete against faraway ports. Nonetheless, such positive forces are counterbalanced by negative ones, which determine “frictions” to the transit of cargo flows and limit hinterland contestability. In particular, the lack of capacity in port and inland infrastructures, high port costs, inefficient, expensive, and unreliable inland connections, all negatively affect port development toward the hinterland, deviating the traffic flows to other corridors and/or ports. When these negative forces occur, logistics players are pushed to find alternative routes with a lower “resistance” in terms of costs and reliability. Consequently, ports that are located on inefficient or low-capacity corridors are in a disadvantageous position.

In summary, gravitational forces and frictions can be assessed through the analysis of costs (considering the overall logistics costs), capacity (e.g., port handling, inland infrastructure, etc.), and the reliability of the port-hinterland system. Nevertheless, this system is affected by other drivers concerning the competitive position of a port in relation to a specific hinterland region, that is,

historical, psychological, political, cultural, institutional, legislative, and personal ones, which are particularly difficult to manage and can largely twist the “perfect” market-based division. In particular, bounded rationality, inertia, and opportunistic behavior are among the behavioral factors that could lead to a deviation from a “distance-decay” optimal solution.

The Active Role of Key Actors in Developing Port Hinterlands

The success of a seaport is based on its ability to cooperate with the maritime cluster and logistics operators in order to exploit all the synergies with the other nodes of the supply chain. In particular, the collaboration between seaports and inland terminals has led to the development of large logistics areas that have arisen both spontaneously, as the result of a slow market-driven process, and carried out by national, regional, and/or local authorities through financial and regulatory actions. These partnerships have proven to be not only of a competitive nature but also of a complementary nature, as they can enhance cargo flows and the competitiveness of the entire supply chain. As regards seaports, the geographical concentration of logistics companies in the hinterland and the development of frequent, well-structured connections lays the foundations to a superior network that positively influences port attractiveness and encourages shipping lines to call and invest in that specific port.

Therefore the development of a broader port hinterland is mainly due to the strategies of maritime and logistics actors. In particular, this section reports the impact of horizontal and vertical relations among shipping lines, terminal operators, rail transport operators, and port authorities (PAs) that aim at supporting the growth of logistics zones and supply chains.

Shipping Lines

Over the last years, shipping lines have implemented internal and external growth strategies aiming at reaching major economies of scale and lowering transport costs. As a result, a significant number of mergers and acquisitions have been carried out in the industry, giving rise to a gradual market concentration. Nowadays, the top 10 carriers control 82.8% of the world market share of the container shipping industry, with 64.5% share controlled by only the top 5 (Alphaliner, 2019). In addition, the formation of global alliances and the deployment of increasingly bigger ships has contributed to reducing the overall ship system costs, as well as to increasing the bargaining power of ocean carriers versus terminal operators and PAs. Nonetheless, shipping lines have to face more demanding shipper requirements that represent a serious challenge for their competitiveness, especially in terms of frequency, reliability and geographical coverage of the services demanded. Therefore due to the inefficiency of many ports of call, liners have gone beyond simple long-term contracts with terminal operators and have started to acquire shares in several maritime container terminals located in strategic positions, in order to directly control and enhance their capacity.

When it comes to the development of a hinterland network, scholars have demonstrated that the proportion of total transport costs represented by intermodal costs is constantly increasing, reaching a range somewhere between 40% and 80%. This supports the notion that inland logistics represents a fruitful area for shipping lines’ growth strategies, due to the possibility of managing the entire transport service and provides more competitive services (i.e., carrier haulage). In this vein, they can further reduce the overall costs related to transport activities (i.e., point-to-point), as well as foster and monitor logistics operational performance. Hence shipping lines have developed rail, barge, and truck services through their own companies (i.e., associated firms or controlled entities) or long-term strategic partnerships with major logistics players. Ultimately, the most ambitious companies have invested in inland terminals and depots aiming at accelerating inbound and outbound container flows.

Terminal Operators

Large global terminal operators have emerged in maritime logistics and inland transport to counterbalance the new dominant position of shipping lines. In this vein, an increasing consolidation has also occurred in this industry, fed by the growing presence of institutional investors (e.g., banks, private equity funds, insurance companies, pension funds, etc.) that have revealed a strong interest in the terminal business. As a result, four worldwide operating companies (i.e., Hutchison Port Holdings, PSA International, DP World, and APM Terminals) dominate the container handling industry, controlling more than 40% of the market share. In addition, for the last two consecutive years, Cosco Shipping Ports, formed by the merger of the two Chinese conglomerates—Cosco Group and China Shipping Group, has reached primacy in the industry (Lloyd’s List, 2018). CS Group achieved this result through the takeover of Greek transshipment hub Piraeus and the Spanish port operator Noatum, and this has considerably enhanced its volume of containers handled. Contextually, terminal operators have strengthened their position in relation to customers by establishing equity joint ventures with shipping companies aiming at co-managing strategic container terminals worldwide. In such a way, terminal operators can secure a more stable cargo base and reduce traffic volatility.

Given the earlier, leading terminal operators have been developing diverging strategies toward extending their business and network. In particular, they have increased the array of logistics services provided, including inland transport (i.e., terminal operator haulage), and their influence throughout the supply chain. Furthermore, they have incorporated several inland terminals in order to create extended gates of seaport terminals. In this vein, they can meet shippers’ requirements, moving closer to the “final customer”, as well as relieve the pressure and congestion of seaport terminals. Hence, terminal operators nowadays appear as key actors in the successful development of port hinterlands.

Rail Transport Operators

Rail transportation is at the heart of the logistics debate, especially in Europe, because it appears geographically, politically and economically fragmented and far away from the realization of a greater intermodal infrastructure for supporting seaport expansion. Nevertheless, the ongoing sectoral liberalisation and the increasing involvement in the industry of major shipping lines, terminal operators, and PAs is helping to bring about a new era in railway transport. Their initiative has proved to be essential in overcoming the limits of rail services that lay with the high entry costs and the fragmentation of cargo flows. In this vein, rail operators have designed more efficient networks by connecting the main nodes of the supply chain that includes seaport terminals and logistics centers located in the hinterland. According to the hub-and-spoke model, cargoes are bundled in the aforementioned logistics nodes and transported by frequent fast shuttle trains. This system has proved to be particularly effective in the European ports of the Northern range, thanks to the well-developed railway infrastructure designed by local and national governments.

The increasing role of rail transport operators in the growth of the port-hinterland is due to their new commercial attitude that fosters the improvement of the services provided (e.g., decreasing the lead time for booking, digitalization of documentation, track and tracing, integration of intermodal services, and door-to-door transport). In particular, the integration of effective railway connections by seaports allow enhancing supply chain performances and promoting intermodality that constitutes a prerequisite for the creation of a broader logistics areas.

Port Authorities

The main objective of PAs is to attract users by providing competitive services to shippers, carriers, and the other logistics stakeholders in the supply chain. In this regard, the current main challenge is represented by hinterland connections that allow PAs to access cargoes far from port boundaries, promote intermodality, and increase their revenues. As well known, ports are pivotal nodes of the logistics chain thanks to their accessibility to the sea and foreland connections. This gives PAs the power to shape hinterland networks and preserve their centrality in the system. Nevertheless, the worldwide transport network, considering both land and sea transport services, is becoming increasingly complex due to the growth in the number of intermodal logistics centers (on the land side) and sea ports, especially transshipment ports that offer valuable routing options for container flows. Indeed, most European container ports are facing a dramatic increase in the relative growth of transshipment traffic flows that requires a strengthening of both port infrastructures and inland long-distance infrastructure. Therefore PAs are expected to develop even closer collaboration with various logistics operators, especially inland and intermodal terminals, in order to foster port competitiveness and intensify demand flows.

Given this perspective, many PAs have launched several projects and initiatives in partnership with inland terminals aiming at creating new logistics zones along the main hinterland corridors. For example, Hamburg Port Authority have invested in rail terminals (Melnik, Budapest, etc.) to support its rail traffic via Potzug, Metrans, and HHCE, whereas Barcelona Port Authority entered into partnerships to expand the port hinterland through the setting up of dry ports and logistics zones (i.e., Toulouse, Zaragoza, and Madrid).

As reported, the success of a port lies with the ability of the PA to collaborate with the maritime cluster and logistics players in order to create synergies for a broader regional logistics network. The development of these logistics poles generates benefits for all the actors involved. In particular, [Rodrigue and Notteboom \(2009\)](#) draw attention to the advantages originating from the cooperation between PAs and inland terminals that include, amongst other things, stronger support for the cargo handling function (due to a better use of port space area); expansion toward the hinterland, and the possibility to fight with competing ports for their market shares; a stronger position for luring (foreign) investments and subsidies because of more attractive, reliable, and frequent integrated hinterland services; the enhancement of intermodal services and better modal split in favor of rail transport; and the simplification of customs procedures.

The Emergence of Port Regionalization

As reported in the previous section, inland distribution is becoming a fundamental dimension of the maritime transportation and freight distribution paradigm. The development of global supply chains has increased the pressure on the main actors of maritime logistics, including shipping lines, terminal operators, rail transport operators, PAs, and inland terminals. In particular, hinterland accessibility constitutes a cornerstone for port competitiveness and, thus, the ability of a PA to develop port systems commercially oriented toward the hinterland is essential for its success.

In this regard, [Notteboom and Rodrigue \(2005\)](#) coined a new concept, known as “port regionalization”, to explain this new phase of growth of port systems, which was traditionally based on the activities confined to the port perimeter. In the regionalization model, instead, inland distribution becomes an essential driver for port competition, as it promotes the emergence of transport corridors and logistics poles. The authors argue that PAs do not lead this process as “motivators” or “instigators”. The process, conversely, derives from the collaboration and strategic coordination between shippers and third party logistics providers. In this vein, PAs are expected to embrace the regionalization process in order to face current port-related challenges, including congestion, limited handling capacity, and growing costs associated with additional traffic. Hence, hinterland accessibility resolves these problems by exploiting logistics corridors and rail transport to accelerate cargo flows and increase the handling capacity of seaport

terminals. Furthermore, regionalization extends seaport terminals toward the hinterland, moving the port closer to its customers and enhancing freight distribution.

Finally, regionalization enables PAs to go much beyond the role of a traditional facilitator. Indeed, PAs undertake an active role in the development of a more efficient supply chain, grounded on inland freight distribution, information systems, and intermodality (Notteboom and Rodrigue, 2005). In particular, PA networking activities represent one of the most peculiar aspects of regionalization. Coordination and cooperation among the maritime logistics actors constitute the pillars of this model and guarantee a valuable competitive advantage to seaports.

Introduction

The application of insights from cluster theories to ports started roughly 20 years ago. The port cluster concept has been applied in practice: the port of Valencia has embraced the port cluster concept, the Chinese government uses the port cluster concept in port planning, the Korean Maritime Institute analyzes the potential of Korea's ports to further develop as logistics clusters and United Nations publications promote the development of port and logistics clusters.

Central to this cluster perspective is the recognition that interdependent firms cluster together in port regions, with various forms of synergies as a result (Porter, 2000). Anyone who drives around in a seaport, takes a boat tour in a port or flies over a port will note that ports are collections of many different activities, such as terminals, warehouses, chemical plants, tank storage, container depots, rail terminals, and cargo processing activities. All these activities locate in the port because of the agglomeration advantages that ports offer. Some of the activities in a port complex are very closely related (e.g., a tank terminal and a refinery), while others are more "loosely coupled" to each other (e.g., a container terminal and a port related ICT company).

It may be hard to imagine in our digital and service driven economy, but the major world cities today have emerged largely because of port activities. London was the world's largest port in the 19th century, to be overtaken by New York, while currently Shanghai is the largest port in the world. All these—and many other world cities such as Hong Kong, Singapore, Tokyo, Buenos Aires, Barcelona, and Venice—flourished in their early age as ports. The arrival, storage, and trade of goods in these port cities led to an agglomeration effect that re-enforced itself: ports attracted other economic activities, which led to population growth, which led to more economic activities, and so on^a.

Synergies From Clustering

All the companies related directly or indirectly to ships and international commodity chains and located in the port area can jointly be considered a port cluster. Synergies arise from the colocation of interrelated companies in ports. Some of these synergies relate to the shared use of infrastructure and services, others to the availability of specialized knowledge and skills.

Some synergies arise "spontaneously," through transactions between the clustered firms. For example, the Siemens plant for rotor blades in the port of Hull will use third-party run terminal facilities for receiving parts and transporting the blades to the offshore wind locations. Siemens will also use energy from power plants in the port and contract transport operators that are established in the port. Engaging in transactions with suppliers and customers in the cluster is attractive since "trade costs" (that include transport costs) for transactions between firms in the same cluster are lower than those of transactions between a firm located in the cluster and another firm from outside the cluster. As another example of spontaneous, transaction-based synergies, because of the "constant market for skill," it is attractive for workers to invest in specific training and education. Thus, specialized training and education programs emerge in clusters and the overall quality of human capital availability is high.

Other colocation benefits arise as a result of *active cooperation* (beyond arms-length transactions) between firms in the cluster. For instance, firms may develop partnerships for innovation, jointly invest in the development of human capital and exchange data in a so-called "port community system."

^a In the words of Fujita, Krugman and Venables (leading scholars in economic geography, Krugman winning a Nobel Prize in Economics in 2009, p236): "Nearly all great cities are major ports (or were at one time), but many have long since ceased to be mainly port cities (. . .). There is nothing paradoxical in the fact that the Erie Canal made New York—and is now no more than a tourist attraction."

Table 1 Stylized characteristics of the transport node and cluster perspective on ports

	<i>Port as transport node</i>	<i>Port as economic cluster</i>
Definition	A gateway through which goods are transferred between ships and the shore.	An economic complex consisting of all firms related to the arrival of ships and cargo and located in one region.

Clustering as a Perspective

The port cluster concept has proven to be a useful “lens” for analyzing ports (de Langen, 2004). In port studies, the perspective that regards seaports as “transport nodes” is well established. The “cluster perspective” complements this “transport node perspective.” With the cluster “lens,” scholars address research issues that are complementary to the established lens of treating a port as a transport node. For example, the cluster perspective provides new insights into the determinants of port competitiveness, such as the importance of intracluster competition for the overall competitiveness of the port. In addition, the cluster perspective can be used to derive additional port performance indicators. Furthermore, the cluster perspective provides a lens for analyzing coordination and *collective action*, analyzed widely in cluster literature and very relevant in ports (de Langen and Visser, 2005). Finally, the cluster perspective yields additional insights regarding the appropriate governance of the port cluster. Table 1 shows stylized characteristics of the “cluster” and “transport node” perspectives.

Components of the Port Cluster

The “borders” of a cluster are somewhat vague in practice, and it may not be very fruitful to try to precisely define the port cluster^b. The port cluster does not just encompass freight operations, but also logistics, manufacturing, and maritime leisure activities (e.g., cruise and marina activities). Even though the borders are inevitably “blurred at the edges,” four components of a port cluster can be distinguished, as shown in Fig. 1.

The function of the port as a transport node is at the center of a port cluster: cargo-handling terminals are the *raison d’être* of the port infrastructure. Since cargo handling is a part of a transport chain, ports also attract transport companies, as well as related specialized activities, such as storage, ship repair, and ship management. All these activities can be regarded as elements of the function of the port as a transport hub.

^bThe cluster perspective has also been applied with a focus on “logistics clusters” (Sheffi, 2012). While there is a clear overlap with port clusters, the “delimitation” of a logistics cluster is different.

Table 2 Activities often included in each of the four components of a port cluster

<i>Transport hub</i>	<i>Logistics value added hub</i>	<i>Manufacturing cluster</i>	<i>Tourism and leisure</i>
Handling and transport of containers (deep sea and short sea), oil & oil products, chemical products, LNG, agribulks, biofuels, cars, iron ore, coal, construction materials, and other commodities.	LCL consolidation and deconsolidation Heavy/special equipment storage & stockholding Stock holding & value adding for slow moving products (B-to-B and to a lesser extend consumer goods). Stock holding & value adding for fast moving products (consumer & B-to-B goods). Fuel blending Refrigerated warehousing	Food processing Energy production Downstream chemicals Upstream metals industries Car/truck manufacturing Shipbuilding & ship repair (including maintenance—all ship types) Downstream metals industries Upstream chemicals	Cruise activities Large & mega yachts Marina Congress, hotel & leisure facilities.

Logistics activities, such as storage, repacking, and assembling are frequently located in seaports. Two reasons explain the presence of logistics activities in seaports. First, cargo is almost always temporally *stored* in ports, because of the scale differences between ships and inland modes (e.g., a 300,000 ton ship vs a 3,000 ton train and a 20,000 TEU ship vs a truck for 2 TEU). This necessity of storage makes ports natural (de) consolidation points and provides a rationale for locating logistics activities (such as blending and repacking) in seaports. Second, a port is an attractive location for logistics activities due to the high (international) connectivity. Thus, goods can be delivered to end markets, both over land and by sea, at lower costs than from most other locations. In addition, many ports are located in metropolitan areas and, thus, are well located for distribution facilities to these metropolitan regions. Included under the label logistics are also *trade activities*. Traditionally, trading and storage (in a port) are closely linked. All major ports were also commercial hubs. Although the strength of links between storage and trade has diminished, for some commodities (for instance fruit, crude oil, and grain), trading and related service activities are still located in the port—and part of the port cluster.

Examples of *manufacturing activities* frequently strongly linked to ports are energy production, steel production, shipbuilding and repair, oil refining, chemical production, and food production. Manufacturing activities in seaports are directly related to commodities handled in the port cluster. Manufacturing is not necessarily limited to large-scale plants; ports may also be attractive locations for small-scale manufacturing, as well as combinations between manufacturing and service activities.

Finally, ports increasingly also function as tourism sites. Ports accommodate cruises and (mega) yachts and may host tourism and leisure facilities such as hotels, restaurants, shops, and museums. In addition, a part of the (former) port land may be a public space. Because of the attractiveness of waterfronts, the potential for tourism-related developments in ports is huge. While such developments may be somewhat isolated from the freight-oriented activities, there are relations with the other port functions. For instance, RoRo vessels carry passengers, part of them tourists, as well as freight. **Table 2** shows activities often included in each of the four components of a port cluster.

Particularities of Port Clusters

Even though the cluster perspective is useful, ports are not the “typical clusters” often described in textbooks and on the mental map of policy-makers, such as Silicon Valley. **Table 3** summarizes the differences between “port clusters” and stylized “tech clusters,” these differences are described in further section.

First, the economic activities in a port are mainly *operational*, since ports, as well-connected pieces of infrastructure for freight flows, are specialized in handling and processing of cargo. This operational specialization implies limited scope for “spontaneous” interactions that may lead to path-breaking innovations. For instance, even the introduction of the maritime container was done by an industry outsider. This is radically different from the widely studied “high-tech clusters,” that are typically associated with spontaneous, noncontractual interactions, and nontradable interdependencies in pitching new ideas and raising venture capital for innovative exploration (Maskell, 2001), often depicted to take place in the coffee corners of Palo Alto or Tel Aviv.

Second, port clusters consist of a *diverse* set of potentially interrelated activities. This is because these port activities are linked to transport and port infrastructure, and include all kinds of activities (terminal operations, transport operations, warehousing, manufacturing, and trading), in all kinds of supply chains (including food, energy, automotive, steel, and so on).

Third, given the international nature of the activities in ports mentioned earlier (transport, logistics, manufacturing, and trade), multinational corporations (MNCs) are dominant players in port clusters. These MNCs have operations in various countries and are thus (more or less) embedded in a variety of port clusters. As a consequence, in most port clusters, only a small part of the clustered firms (or even none) is headquartered in the port. In addition, most MNCs manage operations in a large number of port clusters. This global operational presence in port clusters allows for the diffusion of operational knowledge through the regular transfer terminal managers, but hampers exploration.

Fourth, a “port cluster” developer may play a central role in the governance of the cluster. In most ports, a publicly owned and territorially focused port authority holds a key responsibility in developing the port cluster. Indeed, this organization may think of itself as a “cluster developer.” In many landlord ports, the port authority is run as an autonomous and commercially operating entity, it does not aim at maximum profits, but is more orientated toward creating “value for society.”

Table 3 The differences between “port clusters” and stylized “tech clusters”

	<i>Port cluster</i>	<i>Tech cluster</i>
Type of activities	Operational, capital intensive.	Human capital intensive.
Heterogeneity of clustered activities	High. The type of activities that cluster together in ports range from transport to manufacturing to advanced services. The core driver of clustering is the presence of port infrastructure and the resulting international connectivity for freight.	Low to medium. A technological specialization (medical, media, materials) is often the core of a tech cluster.
Dependence on extra-cluster corporate decisions.	Very high. Most activities located in ports are operational activities that are managed by local branches of MNCs with limited autonomy.	Low to medium. Substantial decision-making powers in the cluster, a relatively high share of the firms are headquartered in the cluster or have a high degree of autonomy.
Importance of “cluster governance” and cluster governance structures	Cluster governance is very important and relatively formalized. Given the need for investments (in tangibles and intangibles) for creating synergies between companies in the cluster (e.g., pipelines, transport infrastructure, a “port community system”) a formalized governance structure is required. In most ports, a territorially focused and often state-owned port development company plays a central role in the governance of the cluster.	Relatively unimportant. The clusters, as well as synergies in the cluster evolve dynamically, market-based initiatives to create synergies dominate (e.g., incubators). The most important collective interest is human capital formation, universities often play a leading role in this respect. Governance is mostly informal and temporal.

The Particularities of Port Clusters; Relevant for Analyzing Port Clusters

The differences between the port cluster and the tech cluster as discussed above have three important implications for the port clusters, as well as for the analysis of such port clusters. First, much more than the “tech clusters,” “port clusters” are vulnerable to technological change, especially given the clear (and sometimes disruptive) impact of new technologies on ports (for instance, think of digitalization, the energy transition, 3D printing, circularity of supply chains).

Second, contrary to most of the work on innovation in clusters, for ports, the core challenge is not so much improving the innovation performance (as measured by indicators such as patents, start-ups, and scale-ups), but enhancing the *absorptive capacity* (Giuliani, 2005) of the port. Because of the characteristics of port clusters (diverse, specialized in operations, and dominated by local branches of MNCs), R&D activities in port clusters are limited and the dominant innovation challenge is the (early) application of new knowledge (e.g., regarding digitalization, recycling technologies, bio-based chemicals, and smart grids). Thus, the vitality of the port cluster depends mainly on its absorptive capacity, which can be defined as the capacity to absorb, enhance, diffuse, and exploit knowledge from extra-cluster sources. The absorptive capacity is determined both by the formation of linkages with extra-cluster sources of knowledge and the intra-cluster knowledge system. For ports, the most relevant indicators are first the investments in the port cluster to apply new technologies in new or established operations and the number and growth of start-ups with “cluster specific” products and services based on new technologies.

Third, contrary to most “tech clusters,” in which governance is rather loose, chaotic, and decentralized, more structured governance mechanisms may be critical to enhancing the competitiveness of port clusters.

The Relevance of Synergy Services and Implications for Cluster Governance

One of the core challenges in developing the port cluster is creating synergies. As argued previously, these do often not emerge spontaneously. *Synergy services* can be defined as services provided to a group of geographically clustered companies that allow these companies to create synergies (Siskos and Van Wassenhove, 2017). Fig. 2 shows examples of such synergy services for each of the four components of the port cluster.

The core challenge of developing synergy services is creating value for users and capturing (a part of) the created value through charges. As the value of the synergy services often increases with the number of users, capturing value directly through pricing may not be attractive, as it reduces the number of users. In addition, users may be deterred by the risk of high costs associated with ending the use of synergy services (e.g., a pipeline), which may allow the synergy service provider to extract an economic rent. Finally, synergy services generally create “value for society” (e.g., reduction of emissions, truck movements, congestion, and the like). This justifies partial public funding for such services. For these reasons, a “for profit approach” for synergy services is often problematic. Consequently, a “not-for-profit approach” may be required, for instance through service provision by a “special purpose vehicle.”

The Business Ecosystem Perspective: Cluster Development in the Strategic Management Literature

In strategic management, the term business ecosystem is used for the network of firms, which collectively produce a system, service, or product that creates value for customers (Iansiti and Levien, 2004). A cluster can be regarded as a territorially focused business

Figure 2 Examples of synergy services in port. Source: *De Langen (2020)*.

ecosystem. A first strategic management insight is that many companies do not compete on their own with other companies, but instead, business ecosystems compete with each other; the ecosystem of companies that constitute the windows, respectively iOS business ecosystems compete. Likewise, the European and North American business ecosystems for design and production of aircraft are competing. Applied to ports, on top of the obvious competition between individual terminal operators in different ports, the competition between the ports as business ecosystems is relevant.

A second insight from strategic management scholars is that some companies actively develop a business ecosystem. Such companies need a specific set of capabilities and have a specific business model and are labeled “keystones.” A keystone develops and regulates the overall function of the ecosystem and, as a consequence, its actions influence the success of all other members. In port clusters, port authorities can be considered as companies that develop a business ecosystem. Port governance structures that enable port authorities to effectively play this role are required. In line with the arguments provided above, an ideal type port governance structure is emerging in which a state owned, but autonomous and commercially operating, port development company develops the port as a business ecosystem and provides various types of “synergy services.”

Ports in Proximity: One Port Cluster?

One of the key questions concerning port clusters is: “in which cases can ports in proximity be regarded as one port cluster and thus are best developed in an integrated manner?” In many parts of the world, initiatives to develop port policies for groups of ports or gateways can be observed: Chinese policy makers regard the Pearl River delta ports as one port cluster and the ports in the Adriatic sea position themselves as one cluster. The state-owned port development companies of Copenhagen and Malmo and Ghent and Zeeland Seaports are even fully merged, even though they are located in different countries.

In the case of the United Kingdom, where port development is mainly done by private companies, mergers between port companies that develop ports in proximity have taken place; there is a natural tendency toward the appropriate geographical scope. Such a mechanism is absent in cases where port development companies are state-owned. Consequently, the geographical scope of publicly owned port development companies is often not optimal. The appropriate geographical scope is one publicly owned port development company for one port cluster. In this case, over investment in similar facilities is prevented, while the port development company remains focused on the development of one integrated port cluster.

Introduction

Port efficiency and effectiveness are normally two complementary components of the broader concept of port performance. Although the academic analysis of effectiveness is more recent than that dealing with efficiency, there is still much to be done, if the sector wants to adequately expand performance measurement programs.

Efficiency, effectiveness, and productivity are related concepts. While efficiency means producing as much as possible with a given quantity of inputs or producing a specific number of goods with a minimum amount of inputs, effectiveness tends to put its emphasis on the users. In the words of various authors, being efficient is about “doing things right,” whereas being effective is about “doing the right things.” The right things are considered those that are identified as such by the users. On the other hand, for a company to be productive, in addition to being efficient, it has to have an optimal scale, that is, an adequate size.

The distinct services offered by a port can be performed by a combination of public and private initiatives. There are a number of port models that show how private participation might be introduced. The most common model is the landlord model in which the port authority (PA), generally public, is the owner of the infrastructure and the remaining services are offered by private port operators. The provision of infrastructure by the PA and the cargo handling by private operators are the most relevant services in terms of port efficiency. Other services can be provided by private port operators working in more or less competitive conditions and, therefore, it is expected to be provided efficiently.

The port industry has been immersed in a process of permanent change for decades. During the last century in many ports worldwide, there was a change of governance toward this decentralized model of port management, along with a greater increase in the presence of private port terminals that would alleviate public budgets and assume part of the risk of port operations. More recently, the increase in ship sizes, the alliances between shipping operators, especially in container traffic, and economic globalization, have all increased competition and led to new services and port logistics. All these changes will be successful if they are accompanied by improvements in port efficiency.

Since the first studies on port efficiency in the 1990s, publications in this area have increased. However, one characteristic stands out in a review of the empirical literature on port efficiency: “diversity.” Studies on port efficiency seem to approach the subject from multiple perspectives. For example, different methodological approaches are used to study port efficiency. The same can be said about other factors in the reviewed studies, including: port services analyzed, inputs and outputs, variables influencing or explaining inefficiency, sample size, and the time period. This “diversity” or variety makes comparisons between research results difficult. However, it is important to note that most articles are dedicated to studying the provision of infrastructure and cargo handling services. In this article, we conducted a review of the methodologies used to estimate port efficiency and effectiveness in order to highlight their characteristics, scope, and limitations.

Port Effectiveness Measurement

The study of effectiveness tends to emphasize the users, who are the final recipients of the services and who tend to influence ports and government in order to improve port performance. Therefore, their perspective should be actively incorporated into the analysis. Efficiency mainly relates to physical aspects and researchers have at their disposal methodologies that allow it to be objectively measured, whereas effectiveness can only be measured against the goals that the users seek and is usually based on qualitative indicators (Brooks and Pallis, 2008).

Normally, any measure that improves efficiency would positively influence the level of effectiveness, but the opposite may not necessarily be the case. Users tend to highlight issues relating to the ability to respond to special requests (working overtime or at

weekends) and relating to cargo damage as important. Maintaining resources ready to respond to potential unexpected situations or security issues may not necessarily be efficient, as these demands may introduce higher costs while managing a similar level of throughput.

The first step involved in the measurement of port effectiveness consists in identifying the main stakeholders in a port. The main customer is obviously the carrier and anybody that buys maritime transportation services, whether in their own name or in that of others, but other agents should also be considered. In fact, many elements in the supply chain may also be clearly interested in the well-functioning of ports, even if they are located outside of their physical location. This can be the case for many intermodal distributors, forwarders, warehouses, and road and rail transport companies.

The second step consists in identifying the main aspects of interest for users. To prepare the list of performance criteria, the authors normally review previous academic studies and then employ surveys directed at users, either to obtain an evaluation of the identified criteria or to ask them directly for those they think fulfil their needs. Once the relevant criteria for users have been identified, the last step involves users, evaluating how a particular port performs in relation to those attributes.

The combination of these two valuations—what aspect is important for the user and how the port behaves in relation to that criterion—can help in identifying the level of performance of a specific port from the users' points of view. A similar procedure can be used to test the performance from the point of view of the PA. If the PA undertakes its own evaluation of the criteria, this internal evaluation can be compared with that of the users, and even with the evaluation of other ports. These comparisons could help in identifying potential performance gaps, especially if they are evaluated over time.

Importance–performance analysis is a technique that has been used by Brooks et al. (2011) for evaluating user satisfaction and service quality, combining what users identify as important drivers with how they appraised a specific port performance. Attributes can be considered determinant, if they help us understand how the user discriminates between various alternatives. The main problem in this procedure is the fact that both elements, importance and performance valuations, are highly correlated and, therefore, generate multicollinearity problems. Normalised pairwise estimation has been identified as a convenient procedure under these circumstances. After rating the importance of the considered criteria, users are asked to indicate the level of all defined attributes for each port. They are also asked to evaluate the general performance of each port using variables like satisfaction, competitiveness, and effectiveness of their services. The determinance importance of each attribute is obtained through a correlation analysis, whereas the general performance of the port is explained by the level of the attributes given by users to the port.

Recently, Ha et al. (2017) proposed the use of a hybrid multistakeholder framework for the modelling of port performance indicators (PPIs). This new port performance measurement (PPM) methodology allows for the integration of a multistakeholder dimension. These authors actually consider a wide group of dimensions ranging from core activities like output—as measured by throughput growth—through aspects like financial strength, user satisfaction, supply chain integration, and sustainable growth. In other words, they do not limit themselves to efficiency and effectiveness measures.

This hybrid PPM model has four steps. The first consists of identifying the needs and aims of the different stakeholders and presenting them as PPIs adapted to each group. The second employs methodologies that solve the problems generated by interdependency, uncertainty of the PPIs and the need to use multigroup multicriteria decision-making methods. The third assigns weights to the different PPIs evaluating their performance for each port. Finally, the PPIs are evaluated with their weights using “fuzzy evidential reasoning” and utility techniques.

Port Efficiency Measurement

Comparing ports in terms of their performance is relevant for economic analysis and crucial for the PA and port operators. The most widely used concept to establish this comparison is productive or technical efficiency. Efficiency arises from the comparison of observed values of a firm's outputs and inputs with optimum values from the optimum evidence provided by other firms. That means efficiency is a relative concept that can vary depending on the firms being compared and that it is necessary to have a standard to compare firms.

Economic efficiency has two dimensions: technical (or productive) efficiency and allocative efficiency. Firms that produce the maximum output from a given set of inputs or, alternatively, firms that use the minimum quantity of inputs to obtain a given output level represent technical efficiency. Firms that use inputs in the right proportions, given their prices and marginal productivity, are known as “allocative efficient.”

The frontier concept, introduced by Farrell (1957), allows us to measure technical and allocative efficiency as shown in Fig. 1A (input-oriented efficiency) and Fig. 1B (output-oriented efficiency). We use the input-oriented approach to introduce technical and allocative efficiency (Fig. 1A). The efficient production function is $Y = f(X_1, X_2)$, where Y is the output obtained with two inputs X_1 and X_2 . If constant returns to scale are assumed, the production function becomes the isoquant (SS') $1 = f(X_1/Y, X_2/Y)$.

Firms Q and P use the same input proportions, but only Q is on the isoquant. Q and Q' are technically efficient, and Q' is also allocative efficient (as represented by the point of tangency between the isoquant and isocost curves). Following an input-oriented measurement (Table 1), it is possible to produce the same quantity of P using the ratio OQ/OP inputs. This ratio ranges from 1 if the company is efficient to 0, if it is inefficient. Comparing Q (in the same isoquant as Q') and R (in the same isocost as Q'), allocative efficiency can be measured as the ratio OR/OQ . If this ratio is 1, the firm is allocative efficient, whereas values less than 1 indicate the degree of allocative efficiency achieved by the company. Finally, economic efficiency can be calculated by multiplying technical and allocative efficiency (Table 1). The degree of inefficiency is calculated as one minus the corresponding efficiency ratio.

Figure 1 (A) Input-oriented efficiency. (B) Output-oriented efficiency.

Table 1 Technical, allocative, and economic efficiency measurement

<i>Input-oriented efficiency</i>	<i>Output-oriented efficiency</i>
Technical efficiency = OQ/OP	Technical efficiency = OP/OQ
Allocative efficiency = OR/OQ	Allocative efficiency = OQ/OR
Economic efficiency = OR/OP	Economic efficiency = OP/OR

In the assessment of port performance, the calculation of technical efficiency prevails. The main reason is that it is less demanding of data, it only requires information on quantities of inputs and outputs, whereas efficiency in costs and allocative efficiency require data on input price or cost.

The Frontier Function

Efficiency measurement is joined to the estimation of a frontier. Once the frontier has been estimated, the efficiency shows how the firm behaves in relation to the performance of the best companies in the industry, if they were faced with the same conditions as the firm analyzed.

Frontier models can be classified according to several criteria. Taking into account the type of data they use, there are models of cross-sectional and panel data. Suppose a port intends to invest in infrastructure and equipment to address a future demand. If the cross-sectional analysis is carried out before the port meets the demand, this port will be classified as inefficient. As the effect of the indivisibilities of the port infrastructure cannot be captured with cross-sectional models, it is advisable to use panel data.

Taking into account the type of variables (physical and/or prices) and the assumed assumptions about the optimization behavior of the companies, the frontier modalities shown in Table 2 can be distinguished. The most elementary assumption is that companies do not waste productive resources. In this case, a production frontier will be estimated, which allows us to obtain an evaluation of technical efficiency.

The choice of the frontier model depends on the hypothesis about the behavior of the producers most appropriate to the case study. Most of the empirical applications to the port industry estimate the production frontier and, therefore, technical efficiency, although there are a few studies that estimate the cost frontier. The main reason is that it is much more difficult to access input price data or financial data on cost and revenues than physical data related to outputs and inputs (e.g., cargo handled, berth length, yard area, cranes, etc.).

Table 2 Frontier and efficiency typology

<i>Optimizing behavior</i>	<i>Frontier</i>	<i>Efficiency</i>
Maximum production	Production	Technical efficiency
Minimum cost	Cost	Economic efficiency in cost
Maximum income	Income	Economic efficiency in income
Maximum benefit	Benefit	Economic efficiency in benefit

Table 3 Characteristics of DEA and SFA

DEA	SFA
• Nonparametric approach • Deterministic approach • Does not consider random noise • Does not allow statistical hypothesis to be contrasted • Does not carry out assumptions on the distribution of the inefficiency term • Does not include error term • Does not require specifying a functional form • Sensitive to the number of variables, measurement errors, and outliers • Estimation method: mathematical programming	• Parametric approach • Stochastic approach • Considers random noise • Allows statistical hypothesis to be contrasted • Carries out assumptions on the distribution of the inefficiency term • Includes a compound error term • Requires specifying a functional form • Can confuse inefficiency with a bad specification of the model • Estimation method: econometric

According to the estimation method, it is possible to differentiate two categories: estimated frontiers through linear programming and those that use econometric methods. The frontier can be defined by assuming a particular functional form for the technology or from a series of properties that it must satisfy, which allows the distinguishing between parametric and nonparametric methods, respectively. Considering the cause of the separation from the frontier, these are classified as deterministic and stochastic. Finally, within the econometric approach it is possible to establish a distinction based on the number of equations of the model (single equations, or systems of several equations).

As in other productive sectors, two approaches have been developed to measure efficiency in the port industry (Charnes et al., 1997; Fried et al., 1993; Kumbhakar and Lovell, 2003): the linear programming method, basically data envelopment analysis (DEA) and the econometric model, mainly stochastic frontier analysis (SFA), with the former being the most used. The main characteristics of these two approaches (Lovell, 1993) are presented in Table 3.

DEA assumes that there are no errors in data collection. For the port industry, this is a quite strong assumption to make. More often than would be desirable, port statistics contain errors in the measurement, especially in the input variables. Bootstrap resampling methods can ease this problem, although with its own limitations. Stochastic frontiers do not suffer from this potential flaw, so it appears to be more appropriate to evaluating efficiency in the port sector when there are suspicions of data collection errors.

Since the first DEA model, a number of improvements have been developed: from constant returns to scale to variable returns to scale, additive model, from radial efficiency measures to nonradial measures, super efficiency models, DEA window model, partial or metafrontiers, etc.

SFA requires the specification of a functional form and makes assumptions related to the distribution of the error term. The Translog production function and normal distribution for the random error and seminormal for the nonnegative random variable associated with technical inefficiency are the most used in empirical applications.

As the first SFA models specified for cross-sectional data, the stochastic frontier approach has evolved in an attempt to overcome the limitations of previous models. Thus, models were designed to accommodate panel data, individual efficiency, variant inefficiency over time, the factors that determine inefficiency, multiple outputs (in stochastic distance functions), etc.

As the interest of researchers moved beyond simply establishing a ranking of ports in relation to efficiency, the focus shifted to explaining the causes of port inefficiency. As a consequence, the models were changed to adjust to the new research objectives.

The DEA approach has been mainly completed with Tobit models, in which the efficiency indices are explained by efficiency explanatory variables and, more recently, with bootstrapped truncated regression. At the beginning, SFA models in two stages was widely criticized, since some of the assumptions established in the first stage are breached in the second. Subsequently, specifications were developed in which the effects of inefficiency are defined as a function of the specific factors of firms that affect efficiency, carrying out the estimation in a single stage.

In the empirical measurement of efficiency in ports, DEA is the approach that is most frequently applied. Ports are heterogeneous entities that include not only port services provided by port authorities, but also services provided by a range of agents and operators. Ports have a multioutput dimension (e.g., services to ships, several types of cargo and passengers). In part, the ease of accommodating multiple outputs explains the prevalence of DEA. The stochastic distance function solves this limitation of stochastic production frontiers without imposing additional restrictions. However, stochastic production functions predominate, perhaps because many empirical works refer to container terminals. Even in this case, it is likely that the terminals also move general cargo, with distance functions being the appropriate approach.

Regarding which approach is best suited to the port sector, some researchers argue that DEA has a business orientation, whereas the econometric approach is more oriented to policy decisions. So one recommendation might be to apply DEA when estimating the efficiency of individual cargo terminals and the stochastic frontier if the estimation relates to port authorities. The characteristics of the data, the port activity analyzed, and the assumptions that can be made will also guide the choice of the efficiency calculation method.

Empirical Analysis in Port Efficiency

In recent decades there has been a continuous increase in the number of academic papers focusing on port efficiency, along with an expansion of the geographic scope of these studies (Cullinane, 2013; González and Trujillo, 2009).

In the literature on port efficiency, two activities are the most studied: the provision of infrastructure service by port authorities and the cargo handling service provided by stevedoring companies and predominantly carried out in port terminals. Regarding cargo handling, most research has focused on container terminals and some has analyzed the aggregate of all container terminals in a port, as the separate output for each company is not available from main secondary data resources. This limits the scope of the studies, since it would be more useful to know the efficiency of each terminal and investigate the causes of the differences between them.

In addition to estimating efficiency levels, research on port efficiency seeks to shed light on the impact of specific events (e.g., port reforms, type of governance, port size, etc.) on efficiency, with the aim to provide evidence that assists policy or management decisions. The diversity of approaches and variables used makes it difficult to compare the works, while offering opportunities to continue analyzing such issues.

Most ports have been involved in regulatory changes that comprise, among other aspects, the decentralization and privatization of port operations. One of the most studied aspects is whether port reforms and the ownership structure influence port efficiency, with inconclusive results. These two aspects are often related to each other, and it is not easy to introduce them into the efficiency analysis. Most of the works that analyze the effects of the reforms do not introduce a specific variable; they simply undertake the analysis in a time period that encompasses before and after the reform, so that the observed variations in efficiency are attributed to the reform, which is a major assumption. Other studies use a naive dummy variable (1 if it is private and 0 otherwise). Classifying ports as public versus private property is very simplistic and hides the complexity of the structure of port ownership and governance, so it would be better to use a more multidimensional approach, such as the port function matrix (Baird, 1995), as has been done in a number of papers.

Under the hypothesis that large ports are more efficient, a number of authors have analyzed this issue. Port size has been approximated by the length of quays, the number of quays and by the output (TEU, tons, or dummy variable). The literature review does not provide conclusive results. Port size is closely related to other aspects such as level of complexity, competition, economies of scale, transshipment traffic, and location. The lack of agreement on the effect of port size on efficiency is perhaps due to the interrelation of all these aspects or can be related to a failure of the exogeneous regressors assumption.

In relation to the role of port competition as a driver of port efficiency, two hypotheses can be contrasted. Ports subject to high competition levels may have an incentive to overinvest in capital, which may lead them at some point to lower levels of efficiency. On the other hand, it can also be argued that the incentive in these competitive environments leads to innovation and, in turn, to an efficiency improvement. The empirical evidence is not yet conclusive, so this is a topic that can continue to be explored.

With respect to the data, the benefits of data panels are highlighted compared to the use of cross-sectional data. While the latter provides static information and reflects differences among units of analysis at particular points of time, the former allows us to observe both the differences between the units of study over time and their evolution. Panel data sets better capture the indivisibilities of the port infrastructure, providing richer information for policy decisions.

We offer a detailed and critical description of the main variables used to measure port output and inputs, as well as the variables that determine port efficiency.

- In spite of the fact that ports have a multioutput dimension, most authors focus on cargo as the port output, mainly measured in tons, whereas a few use a monetary approximation. Recent works also include the number of vessels, the berthing time, and considering the cruise boom, the number of passengers is also gaining special relevance.
- It is useful to distinguish several types of cargo: solid bulk, liquid bulk, break bulk and containers, each one requiring specific facilities, and services. However, not all the papers reflect these differences in cargo. Monoproduction is used in two cases. Papers that focus on a port as a whole use total throughput in tons. When the objective is to analyze container terminal efficiency, the output is containers (in tons, number or TEUs). However, as general cargo is also usually handled in container terminals, it might be useful to distinguish between gateway traffic and transshipment traffic as different outputs. However, the lack of disaggregated data have led to the use of global measures in many of the studies.

In relation to output, the recommendation is to try to reflect the multiproductive nature of port services; both DEA and the stochastic distance function allow for this.

Inputs can be measured through physical and monetary approaches. Most of the research use capital and labor to carry out the port activity, although there are differences in the way of measuring them.

- The capital factor is the the most controversial input. This factor includes the docks (length and depth), terminal area, and mechanical equipment. Quay length and depth indicates the ability of the port/terminal to accommodate ships. Larger quays will be able to serve larger vessels with higher loading levels. The port draft constitutes an entry restriction on certain types of ships. Likewise, the terminal area also represents the storage capacity of the port. The mechanical equipment refers both to the cranes needed to handle the cargo from/to the ships and the equipment involved in the organization and storage of the merchandise in the terminal. Most studies measure capital in physical terms, although some of them use monetary approximations, such as the net value of capital or capital depreciation.

- Depending on the type of cargo, the equipment differs. Containers are handled via cranes on terminal docks (ship-to-shore cranes) or on board the ship (ship cranes) and their storage is done by other equipment (e.g., tow truck, reachstacker, straddle carriers, forklift trucks). Rolling loads do not require cranes. Bulk cargo is handled using a system of suction pipes or grab cranes (both on dock and on ship). Liquid bulk can be found both in liquid and in gaseous state, and its discharge (or loading) is carried out by pipes.
- The inclusion of mechanical equipment in an efficiency study is a challenge. The existence of different types of cranes with disparate characteristics – such as outreach, speed or maximum lifting capacity – makes it difficult to compute them. Something similar happens with storage resources. One of the main drawbacks of the data set is that they do not reflect the technological improvements in cranes.
- Several measures are used to include mechanical equipment in efficiency studies. Although some use the number of operative hours, the most common practice is to include the number of cranes available, differentiating by typology in some cases (quay cranes, yard gantries, and straddle carriers). Other studies include the load handling capacity of the cranes, also differentiating by typology, which makes more sense.
- In summary, it is necessary to develop approaches that capture the technological characteristics of modern cranes. It is always preferable to use the load capacity of the cranes than the number of cranes. If data are available, it would be ideal to work at a level of disaggregation that reflects the lifting capacity of the different types of cranes. If it is not possible, it is necessary to develop an index that reflects all these characteristics and allows comparison between the different cranes.
- Regarding labor input, two types of workers are included: those who work for the port authorities and the stevedores, who work for the cargo terminals. The labor input can be measured as numbers of employees, hours worked or work shifts, as well as in terms of remuneration or labor costs, with the most common being the number of workers.
- Measuring the port workforce presents difficulties. While information concerning the employees of a PA is relatively easy to find in annual port reports, to obtain data regarding the stevedores is difficult, especially when comparing different countries, because it is often necessary to carry out questionnaires in ports and terminals, whose response rate is usually low. This has led, in some studies, to use the employees of the PA to define the service of handling cargo, which does not reflect the reality of the service and can lead to incorrect results. Other papers, to avoid the labor factor, argue that there is a constant relationship between the number of cranes and stevedores, so they use a ratio to the number of cranes as an approximation of the number of stevedores. However, this relationship may be affected by technological issues and the authors themselves warn that this assumption limits and conditions the results obtained.
- Some research also add other input variables. These are measured mainly in monetary terms to capture inputs such as energy, intermediate consumptions, etc.

Conclusion

Making comparisons between the results and conclusions of research that measure efficiency in the port industry is not an easy task. The diversity of methods and specification of the functions, the differences in the variables of inputs, outputs, determinants of efficiency, the different time periods and countries compared all add to the difficulty and make it highly problematic to achieve robust results.

It is necessary to define as sharply as possible the port activities under study, which requires arriving at a balance between the number of necessary variables and the number that the sample and the models are capable of supporting.

It is possible to continue advancing in empirical research to reach a degree of consensus in relation to the determinants of efficiency and even develop issues that the literature has not addressed sufficiently, such as questions about quality, user time (berthing time, waiting time and delay time), emissions of greenhouse gases, climate change, etc.

In terms of effectiveness, more evidence about this indicator is also welcome. In addition, effectiveness can be considered a complement to efficiency, so that taking into account the objectives of users would greatly help improve efficiency. It seems clear that if the port is not effective, it can hardly be efficient.

Introduction

Containerization transformed the way general cargo is transported in the 1970s and facilitated the globalization of supply chains thereafter. The standardization of container dimensions and twist locks for lifting enabled the mechanized transfer of containers between ships, trucks and trains and greatly reduced the workforce in ports from large numbers of dockers working in gangs to a much smaller number of drivers of cranes and vehicles. It was then a small step to the automation of container handling, replacing some drivers by control room operators remotely controlling equipment or managing exceptions for automated equipment. Experience suggests that automation approximately halves the workforce, but the main gains are in terms of reliability and safety.

To date, the investment required to automate container terminals is huge and the returns on investment have been modest. As automated equipment becomes more “off the shelf”, its cost will fall and the equipment control software will improve in reliability and efficiency. As a consequence, container terminal automation is expected to continue its slow spread, not just to more ports, but also to cargo handling upstream and downstream of the port, and in documentary transfer which finances and facilitates international trade. This chapter looks at container terminal automation in detail, describes the pros and cons of various forms of automation, and anticipates future developments for the container port of the future.

Containerization

The mechanized handling of general cargo that containerization facilitated also opened the possibility of automating the loading, unloading and stacking of containers. The containerization of general cargo revolutionized breakbulk shipping, bringing with it the consolidation of those shipping lines carrying containers and massively reducing the labor requirement of those ports handling containers. The result was a period of industrial unrest in the 1970s among those dock workers no longer required for loading and unloading ships, who were replaced by very much fewer drivers of cranes and vehicles. The sheds used to protect loose cargo from the elements were replaced by yards to store containers. The larger space requirement led to some container terminals relocating to sites where more land was available. From the seafarer perspective, life on board container carriers also lost some of its appeal as the ships spent hours rather than days in port, but the supply of seafarers from developing countries like the Philippines has so far sustained container shipping (see Phillips, 2014, for a short and readable account of the impact of containerization).

Container Terminal Automation Technologies

The potential to automate the handling of containers in ports was evident from early on, starting with stacking cranes in the yard. Initially attention was focused on rail-mounted gantry cranes, referred to as RMGs, because of the positional accuracy offered by rails. The Delta Terminal of Europe Container Terminals (ECT) in Rotterdam is believed to be the first terminal where Automated Stacking Cranes (ASCs) entered operation in 1993 (PEMA IP03, 2012). Despite a slow start, ASCs have gradually spread, to the extent that by 2016 there were over 1100 in operation around the world. The technology is now standard and as a consequence the cost has fallen and reliability improved (PEMA IP12, 2016).

There are two types of ASC in common use. In Europe, the end loading/unloading ASC working a block of containers 6–10 containers wide and between 28 and 48 TEU (20 foot equivalent units) long positioned perpendicular to the quay appears to be preferred (Kemme, 2012). There would generally be two ASCs per block, with one serving the quay and the other serving the landside. This layout works well when the proportion of transhipped containers is low. It has the advantage of separating the internal

vehicles serving the quay cranes from the external vehicles collecting and delivering containers on the landside, with safety benefits for drivers. In Asia, however, a block layout parallel to the quay worked by side loading ASCs is preferred. The block may be wider (10–12 containers). A cantilever on the ASC allows containers to be loaded or unloaded from a trailer alongside the crane. This layout is less sensitive to the proportion of transhipped containers. When there are cantilevers either side of the ASC the internal vehicles can be separated from the external vehicles, with safety benefits for vehicle drivers. The side loading ASCs are heavier than the end loading ASCs, but travel less, saving energy and track wear and tear. Although in both layouts containers are generally stacked 5 high, the yard density achieved with end loading ASCs is higher because of the absence of vehicle lanes between the blocks (PEMA IP03, 2012).

Automation of the horizontal transport between the quay and the blocks in the yard has not reached the same level of maturity. Initially Automated Guided Vehicles (AGVs) were deployed by ECT in Rotterdam in 1993 (PEMA IP12, 2016). After resolving initial problems encountered in Rotterdam, AGVs were deployed in HHLA's CTA terminal in Hamburg in 2002. However, AGVs cannot load or unload themselves, so must be located beneath the ASC or quay crane during loading or unloading. Significant gains in vehicle productivity are possible when crane and vehicle activity are decoupled. One possibility used in a number of terminals is to decouple the ASC and AGV by use of a rack. The ASC unloads an export container on to a rack, a lift-AGV slides under the container, lifts it off the rack from below, and transports it to the quay crane. The process can also be reversed for an import container, however racks cannot be used in conjunction with quay cranes. Lift-AGVs have been deployed at APMT's Maasvlakte II terminal, Rotterdam, in 2015 (PEMA IP12, 2016).

Another possibility is to use shuttle carriers, reduced format 1 over 1 straddle carriers, which can pick up a container left on the ground by an ASC or a quay crane. Shuttle carriers at present have drivers. An operational disadvantage of the shuttle carrier over the lift-AGV is that the former requires a wider lane. On the other hand, racks cannot be easily used in combination with quay cranes, because ships can change position.

New forms of automated horizontal transfer between the quay crane and yard storage block are being developed. After the implementation of Autostrads (driverless straddle carriers developed by Kalmar) in Patrick's Brisbane Terminal 2002, this technology has matured, and is in operation in the Patrick Terminal, Port Botany, Australia, since 2015. Having successfully automated the straddle carrier, it is a small step to the automation of the shuttle carrier. Since 2017, automated shuttle carriers have been in operation in Melbourne's VICT facility.

Elsewhere in the terminal, remote-controlled RMGs with rotating 'spreaders', the device that locks on to the container, have been used to load and unload trains. In APMT's Maasvlakte II terminal, lift-AGV have been used to transport containers to and from the railhead (PEMA IP12, 2016). The automation of quay cranes has only been partial so far, because of ship movement and the safe setting or removal of twistlocks on the ship. However, HHLA's CTA terminal in Hamburg pioneered an automated second trolley, which moves containers between an intermediate lashing platform on the quay crane and AGVs. This facilitates parallel working, since containers can be lifted from a ship to the lashing platform at the same time as containers are lifted from the lashing platform to an AGV. The quay cranes in APMT's new Maasvlakte II terminal are equipped with spreaders to lift containers to or from the ship up to four 20 foot containers at a time and spreaders capable of loading or unloading lift-AGVs at up to two 20 foot containers at a time.

Remote-control is revolutionizing the work of the quay crane driver. Rather than sitting in a cab high up in the crane and peering down between his/her legs at the spreader below, the driver can sit or stand in the comfort of the control room, operate one or more cranes simultaneously, switch to a colleague for a break, and consult when a problem arises.

Container Terminal Automation Challenges

Automation and remote crane control approximately halves the workforce. In 2014, the Patrick Terminal of Port Botany, Australia, employed 436, however after automation in 2016, when conventional straddle carriers were replaced by driverless Austostrads, the workforce fell to 213 (Hellenic Shipping News, 2019). Safer well-paid jobs remain in the control room, providing a basis for a negotiated settlement with labor unions. A study by Prism Economics and Analysis, commissioned by the International Longshore and Warehouse Union (ILWU) Canada and quoted in Hellenic Shipping News (2019), found that the automation and digitization of container terminals in British Columbia could lead to significant job losses, reduce tax revenues and impact the local economy. This was a major issue in contract negotiations between the ILWU and terminal operators, which however were resolved after a short strike.

Another major challenge in automation has been linking the Equipment Control Software (ECS), which is generally provided by the equipment suppliers, with the Terminal Operating System (TOS), which keeps track of container location and status and increasingly initiates jobs. The TOS is transitioning from a database to a workflow optimizer and an initiator of jobs for the ECS to execute. The TOS increasingly optimizes slot allocation and storage/retrieval schedules.

Slow Pace of Container Terminal Automation

Since the first example of port automation in 1993, the spread of the technology has been slow. Chu et al. (2018) estimate that by 2018 there were almost 40 fully or partially automated container ports around the world, with at least US\$10 billion invested in such projects. After the removal of initial niggles and software bugs, container terminals have proven to be safer and more reliable after

automation. However, [Chu et al. \(2018\)](#) reported that the return on invested capital and productivity has disappointed industry managers. This contrasts with the mining sector, which also involves heavy equipment working outdoors, where early adopters of automation have experienced productivity improvements of 20%–40%. Nonetheless, the survey of port terminal managers conducted by [Chu et al. \(2018\)](#) anticipates more automation in the future.

The automation of container terminals can be characterized by four stages ([Chu et al., 2018](#)):

1. Port 1.0: “Management by hero”, where managers make decisions supported by a TOS, which keeps track of containers in the yard.
2. Port 2.0: “Management by process”, where the TOS allocates jobs to cranes and vehicles, and managers supervise the process.
3. Port 3.0: “Management by exception”, where the ECS interacts with the TOS to generate, schedule, allocate and execute jobs carried out by automated cranes and vehicles, leaving the managers to deal with exceptions where automation cannot cope.
4. Port 4.0: “From manage to orchestrate”, where documentary exchanges are performed electronically and automatically, and where automation is extended beyond the port upstream and downstream in the supply chain.

While Port 3.0 is now technologically well-established and spreading slowly, Port 4.0 is now emerging.

Green Ports and Automation

Steps are currently being taken to reduce the environmental footprint of ports. In general, this involves the electrification of cranes, *cold ironing* (switching to landside electricity supply when at berth), and the use of hybrid straddle carriers. Electric AGVs are coming into use, for example in APMT’s Maasvlakte II terminal, but this involves a complicated automated battery swapping system. Battery powered straddle carriers pose a challenge because of the distance traveled and the lifting. However, battery powered shuttle carriers look promising (see [Leskinen and Hägglom, 2019](#), for a full discussion on the electrification of port equipment).

The “greenness” of electrification depends on the extent to which electricity is generated from renewable energy sources, in particular wind turbines and solar panels. Ports frequently offer large roof areas suitable for solar panels and piers or breakwaters suitable for wind turbines, so the load on the electricity grid can be reduced. The use of regenerative technology to reclaim electricity when lowering containers or when vehicles brake can also reduce the load on the electricity grid, but will require intermediate storage of electricity in batteries. Fuel cells are a promising technology for the future, but a supply chain for hydrogen suitable for vehicles in ports is not currently available.

Automation and electrification are synergetic. In combination they offer possibilities for optimizing the use of electricity. Machine acceleration and deceleration, top and cornering speed as well as loads can be adjusted to improve the overall efficiency of the electric powertrain. Automation and digitalization enables the scheduling of charge cycles as part of the routing of vehicles, and the entire operation can be optimized incrementally through machine learning ([Leskinen and Hägglom, 2019](#)).

Future for Container Terminal Automation

International trade relies on the exchange of documents between the buyer and seller, or their respective banks. The seller would like to be paid when shipping the cargo, while the buyer would not like to pay until the cargo (or more specifically, the entitlement to the cargo) is received. The classic and most reliable way to fund international trade is the *Letter of Credit* (L/C). The buyer goes to his/her bank, orders a L/C, and sends this to the seller’s bank. The L/C lists documents the buyer requires before paying. Key among these is the *Bill of Lading* (B/L), which is both the receipt issued by the shipping line to the exporter when loading the cargo and the title document that enables the importer to take possession of the cargo upon arrival. When the buyer’s bank receives the L/C, B/L and other documents (like certificates of origin, warranties, inspection certificates, etc), the buyer’s bank pays the seller’s bank.

There are simpler, and therefore cheaper, forms of documentary exchange, but they are less secure. For example, under the *sight draft* procedure, the buyer’s bank holds on to the B/L and other documents received from the seller (or seller’s bank) until payment has been made, but there is a risk that the buyer decides not to purchase the cargo after the seller has shipped it, leaving the seller with unsold cargo “at sea”.

Increasingly, documents are exchanged electronically. Consequently, distributed ledger and encryption technologies, in particular blockchain technology, is receiving attention as a way to ensure secure electronic document exchange and to automate document checking and payment ([DHL, 2018](#)). To date a number of platforms have been developed, but their use is spreading slowly. The best known is TradeLens, developed jointly by IBM and Maersk, but according to a news report ([Wee, 2018](#)) take-up among other shipping lines has been limited, perhaps due to a lack of trust in the impartiality of the platform given the involvement of Maersk.

An interesting example of the extension of automation beyond the port, also a feature of Port 4.0, is the use of hybrid AutoStrads (driverless straddle carriers developed by Kalmar) to connect the rail terminal with adjacent warehousing in Sydney’s new Moorebank intermodal terminal ([Kalmar, 2019](#)). When the facility is finished, a significant number of containers offloaded at Port Botany will be transported to Moorebank intermodal terminal by train and then transferred automatically to warehousing in the adjacent logistics park. The Port 4.0 vision will be automation “from ship to shop”, to include the documentary exchanges

involved. This vision will then match Australia's iron ore mining and exporting industry, where automation is being extended "from pit to port" (Issa, 2019).

Biography

Michael Bell is the professor of Ports and Maritime Logistics in the Institute of Transport and Logistics, at the University of Sydney Business School. Prior to this, he was for 10 years the Professor of Transport Operations at Imperial College London and for the final 5 years at Imperial the Founding Director of the Port Operations Research and Technology Centre (PORTeC). He graduated from Cambridge University with a BA in Economics and obtained an MSc in Transportation and a PhD on Freight Distribution from Leeds University. His research and teaching interests span ports and maritime logistics, transport network modeling, traffic engineering, and intelligent transport systems. He is the author of many papers, a number of books (including *Transportation Network Analysis*, published in 1997), was for 17 years an Associate Editor and now an Editorial Board Editor of *Transportation Research B*, the leading transport theory journal, was an Associate Editor of *Maritime Policy & Management* and is currently an Associate Editor of *Transportmetrica A*.

Introduction

The container shipping industry has grown tremendously since its emergence in the 1950s. Today, the largest container ports in the world handle millions of containers per year. The largest ocean-going container ships can carry more than 20,000 container units each. To handle the huge flows of containerized cargo, port facilities have become billion dollar investments that provide the infrastructure for quickly serving even the largest container ships, for intermediate storage of thousands of containers, and for handling dozens of trains and thousands of container-carrying trucks every day. The typical workflow of a container terminal is illustrated in Fig. 1. At the seaside, ships moor at berths for being served. The unloaded import containers are transported to the yard area where they stay (typically for a couple of days) until they are further transported into the hinterland by trucks, trains, or barges. Hinterland traffic based on road and rail transportation requires specialized handling facilities configuring a hinterland interface, while inland waterway transportation typically uses the facilities given at the seaside area. Generally, containers carrying export goods take the opposite way through the terminal, that is, they arrive at the port from the hinterland by truck, train, or barge, stay in the yard, and are then loaded onto their designated container ship.

Terminals require specialized, powerful crane equipment at the seaside area, in the yard, and at the hinterland interface in order to stack containers and lift them onto transport vehicles. A highly productive usage of this equipment calls for an optimization of crane operations in container terminals. The corresponding optimization problems have been investigated in great detail in recent years. With this article, we provide a fundamental description of the crane technology used in container ports and the operational optimization problems that occur when using this equipment.

This article is organized as follows. In Section “Crane Technology” we provide technical details of the most relevant types of cranes, namely, quay cranes (QCs) that are used at the seaside and gantry cranes that are used in the yard and at the hinterland interface. A discussion of the fundamental optimization problems in the operations management of QCs and gantry cranes is provided in Sections “Optimizing Quay Crane Operations” and “Optimizing Gantry Crane Operations.” Finally, we briefly outline topics for future research in Section “Research Trends.”

Crane Technology

Quay Cranes

QCs are deployed at the seaside of a container terminal for retrieving containers from ships and for loading containers onto ships (Fig. 2A). The largest container ships in service nowadays can carry more than 20 rows of containers next to each other in a bay and up to 24 containers on top of each other (e.g., ships from the Triple-E class). Hence, for serving such ships, QCs have to have an outreach of more than 60 meters and a lifting height of 40 meters. Unloading a container from a ship requires placing the crane's spreader on the container where it is fixed using twistlocks before being lifted by a hoist. A trolley then moves the container to the

Figure 1 A schematic view of a container terminal.

shore where it is lowered to the ground or onto a transport vehicle and released by unlocking the twistlocks and lifting the spreader. The loading of a container is performed using the inverse procedure, starting at the quay and ending at the ship. One such transfer operation is referred to as a “move.” The number of moves per hour is the major productivity measure for QCs. Typical productivity rates in practice are 25–35 moves per hour. Up to now, QCs are still manually operated by crane drivers, but numerous technical innovations may lead to (partly) automated crane operations and a general increase of crane productivity in the future. Advanced technologies already existing are twin-spreaders for handling two container units in one move, dual trolley QCs where one trolley serves the ship and hands over containers to a landside trolley putting them onto transport vehicles, and remote control, which enables one human operator to operate multiple QCs in parallel. A general difficulty observed by crane operations control is that QCs are mounted on rails for being moved alongside the quay. This has the effect that QCs cannot overtake each other, but have to keep their relative position at the quay at all times. Furthermore, due to their geometry, a safety distance has to be kept between cranes, which means that no two cranes can operate at adjacent ship bays at the same time. Needless to say, technical crane operation rules are able to considerably reduce crane productivity. For this reason, research on optimization in crane scheduling puts a strong focus on these constraints.

Gantry Cranes

Gantry cranes are used for stacking and retrieval operations in the container yard and for unloading and loading containers from/to trains at the hinterland interface of a terminal (Fig. 2B and C). Gantry cranes used in the container yard of a terminal are also called yard cranes (YCs). The container yard is partitioned into yard blocks, where each block consists of a number of container rows with lengthwise-arranged storage positions (the so-called bays) (Fig. 2B). A gantry crane spans such a block, which means that the number of rows in a block is determined by the width of a crane. Furthermore, adjacent blocks need to be separated by traffic lanes. Gantry cranes can be rubber-tired (RTGCs) or rail-mounted (RMGCs). RTGCs can span up to eight rows of containers. RMGCs are somewhat larger and can span 10 or even more rows. Although RMGCs support a higher overall storage density for the yard, the advantage of RTGCs is that they are mobile and can be moved relatively freely among different blocks. If automated, the gantry crane is called an automated stacking crane (ASC). Gantry cranes can stack containers up to six tiers high where the topmost tier typically remains empty for moving lifted containers. In a train area, gantry cranes span multiple rail tracks, which allow them to serve a number of trains in parallel. Gantry cranes use the same technology (spreader, twistlocks, hoist, trolley, etc.) and similar work processes for moving containers as previously described for QCs. However, while QCs reposition containers only along one axis (ship-to-shore), gantry cranes reposition containers along two axes. They can move a container from one row to another using the trolley, while the crane itself remains at its position. They can also move containers lengthwise along the block by letting the crane travel with a lifted container. This allows gantry cranes to reposition containers among any stacks in a container block. The horizontal transport vehicles carrying containers to/from the yard block can be served either at the two ends of the block, or are served by the YC beneath a bay, provided an outer row of the container block is left empty to serve as a parking lot. The former layout allows the stacking of more containers in a bay, but requires additional movement of YCs, while the latter option has a lower storage capacity but faster crane operations.

The number of container moves per hour is also a relevant productivity measure for gantry cranes. However, this measure can strongly vary for gantry cranes, as the durations of individual container moves depend on the distance between the particular retrieval and stacking positions in the yard block. Several technological innovations have been developed to make gantry crane systems more productive. Different to QCs, gantry cranes can already be run on an automated or semiautomated basis today. In combination with remote-control automation, this enables large container yards to be run by only a few human operators. Another approach often found

Figure 2 Quay cranes and gantry cranes. (A) Quay cranes at the seaside. (B) Twin gantry cranes in container yard. (C) Gantry crane at train interface.

in practice is to deploy two gantry cranes in a yard block instead of just one, in order to increase the number of containers handled in the block per hour. If the two cranes are of the same size (the so-called twin cranes), each of them operates at one end of the yard block, also called landside and seaside cranes (Fig. 2B). Obviously, twin cranes cannot pass each other and have to keep a safety distance at all times. In such a system, if a container has to be repositioned from one end of the block to the other, either the noninvolved crane has to move away (if possible), or the container is placed at an exchange point from which the other crane picks it up. If the gantry cranes are of different size (the so-called dual cranes), the smaller crane can pass beneath the larger crane. In this kind of system, both cranes can reach every position in the yard block, but they are not allowed to operate at the same yard bay at the same time.

It should be noted that a terminal might also employ the so-called straddle carriers that can lift, drop, and carry containers to any position in a terminal. Hence, straddle carriers can be used for horizontal transportation of containers as well as for stacking and retrieving operations in the yard and at the hinterland interface. Particularly for smaller terminals, straddle carriers are an interesting alternative to circumvent major investments in gantry technology, which in general is profitable only if highly utilized.

Optimizing Quay Crane Operations

The QC resource of a container terminal is the subject of several strategic, tactical, and operational decisions. For example, when building a new terminal or extending an existing terminal, an equipment selection problem is faced regarding the type and number of QCs that are to be procured (Meisel and Bierwirth, 2011a). Decisions on equipment are typically made in response to changing market conditions (e.g., growing vessel categories), sometimes even in accordance with the demands of shipping companies. They enable a terminal to gain competitive advantage against other terminals in the port or in the region. An important tactical problem is how to dimension the workforce of the terminal to meet the workforce demand in the daily operations. A crucial operational question is how to utilize the available cranes for highly productive transshipment processes and a fast service of ships. This challenge is related to two operational optimization problems, the quay crane assignment problem (QCAP) and the quay crane scheduling problem (QCSP), which are described here in more detail.

Quay Crane Assignment

The QCAP is to assign a number of QCs to each ship that is served at the terminal. Next to the number of cranes, the QCAP also has to decide on the specific cranes to be assigned to a ship. Smaller ships are typically served by one to three cranes, while larger ships can be served by up to six cranes simultaneously. Since QCs are a scarce resource of container terminals, the QCAP is especially relevant if multiple ships are served simultaneously. Clearly, the total number of cranes available has to be respected at all times in the QCAP. A further constraint can be that a ship operator and the terminal operator contracted a least number of cranes that must be assigned to a ship. The number of cranes assigned to a ship might be constant for the whole service process (the so-called time-invariant QC-to-vessel assignment) or it might change in the course of time (the so-called variable-in-time QC-to-vessel assignment). While time-invariant assignments are easier to plan and implement at a terminal, variable-in-time assignments give more flexibility in utilizing the QC resource. Eventually, all ships must receive sufficient QC hours for loading and unloading based on the total number of container moves to be executed. Additionally, it needs to be considered that QCs have to keep safety distances and cannot pass each other because they are rail-mounted. These restrictions account for the fact that cranes can interfere with each other when moving to dedicated bays. Consequently, assigning more and more cranes to a ship increases the probability of crane interference and reduces individual crane productivity. As the number of cranes assigned to a ship determines how fast a ship is served, the QCAP has significant impact on the departure times of ships and, thus, on the service quality achieved by the terminal. Therefore, crane assignment is a crucial decision, especially if a large number of ships are served in parallel. A typical objective in crane assignment is, therefore, to minimize tardiness in ship departures.

Assigning not just a number, but specific cranes, to a ship is of relevance, if not all available cranes are in use. Consider, for example, a terminal with eight QCs and two small ships to be served with three QCs each. The specific cranes to use might be 1–3/4–6, 1–3/5–7, 1–3/6–8, 2–4/5–7, 2–4/6–8, or 3–5/6–8 as the rail-mounted QCs have to keep their relative position at the quay. In such a situation, the cranes to use are selected such that the movement of cranes to the ship positions or the setup operations of cranes are minimized.

In the scientific literature, the QCAP is rarely investigated as a problem on its own. Due to the interdependency with berth allocation and quay crane scheduling, the QCAP is typically combined with one of these problems by merging the corresponding decisions, constraints, and objectives into an integrated optimization problem. In particular, the integrated berth allocation and crane assignment problem has been studied intensively. Especially for terminals with continuous quays (one long, straight quay wall) decisions about where to berth ships and which cranes to use are highly interrelated. An explicit QCAP is not relevant for terminals where quays are viewed as discrete resources. Here, every ship is assigned exclusively to one of a number of available berth segments, each equipped with a fixed set of QCs.

Quay Crane Scheduling

The QCSP is to determine starting times and the respective cranes for all loading and unloading operations of containers belonging to a certain ship. The predominant objective of this optimization problem is to minimize the latest completion time among all crane

tasks, also called the makespan of the schedule. This objective coincides with the minimization of a ship's handling time and, as such, strives for short port stay times and on-time departures of ships. Further objectives to be considered in the QCSP are, among other things, the minimization of the total finishing time of cranes and the minimization of unproductive crane movements. Such goals mainly aim at reducing crane operation cost, which, in practice, receives attention only in the case that an on-time departure is assured for a ship.

The basic constraints of the QCSP are quite similar to constraints met in general scheduling problems: every loading/unloading task must be assigned to exactly one QC, each QC can process only one task at a time, and task processing is non-preemptive. More specific constraints of the QCSP concern, for instance, the initial positions and ready times of the QCs. Even time windows might be given that restrict the period at which a crane is available for serving a ship. Ready times and time windows typically follow from the QCAP, which is solved prior to the QCSP.

The fact that QCs are rail-mounted leads to a set of mandatory interference constraints. Most fundamental is the non-crossing constraint, which ensures that cranes keep their relative positioning at the quay at all times in the crane schedule. Some QCSP models also consider a safety requirement, saying that a minimum distance (typically measured as a number of ship bays) is kept between any adjacent QCs at all times in the crane schedule. Non-crossing is often ensured by moving all cranes in parallel into the same direction along the ship (from bow to stern, or from stern to bow) throughout the service process. This leads to the so-called unidirectional crane schedules. More advanced models also care for the stability of the ship during the service process, which might be endangered in a unidirectional loading/unloading process.

The containers to load and unload for a ship are given in the ship's stowage plans. From this, a QCSP can be derived which determines a schedule for each single container move to be executed (Meisel and Wichmann, 2010). However, this becomes computationally intractable if a large number of containers (probably several thousands) have to be handled for a ship. To reduce complexity, practicable QCSP models typically cluster the huge set of containers into the so-called transshipment tasks, which aggregate subsets of operations to be scheduled. Transshipment tasks can refer to: stacks of containers (the so-called stack-level); several groups of containers in the same bay (group-level); all containers to load and unload at a certain bay (bay-level); or a subset of the bays (area-level). The most prevalent aggregations found in the literature are the group-level and the bay-level. These aggregations significantly affect smaller task sets for the QCSP without losing the flexibility to balance the total workload among the available cranes effectively. In the group-level aggregation, there are typically precedence constraints involved to ensure that groups of import containers are unloaded at a bay before groups of export containers are loaded (Kim and Park, 2004; Bierwirth and Meisel, 2009). The more detailed stack-level and container-level aggregations are used to model advanced loading techniques like crane double cycling or container reshuffling, where the scope is restricted to a single ship bay. Such models have to be assembled and solved for each bay of a ship individually. Then the detailed schedules obtained are inserted into the overall crane schedule that is built for the entire ship service process.

A further distinction of QCSP models is whether a crane schedule is determined for a single ship or for a set of ships served in parallel at the terminal. QCSP models of the latter type support the possibility to transfer cranes from one ship to another during service, which implicitly solves a QCAP. Here, the moving speed of QCs becomes a crucial parameter. Multi-ship models usually strive for a minimization of the total weighted completion time of ships. Other advanced models integrate quay crane scheduling with stowage planning or with horizontal transport management. Stowage planning is closely related with crane scheduling as it makes decisions on where to locate containers onboard a ship. Implementing the stowage plans for the bays obviously impacts the workload of the QCs as given in the QCSP. Horizontal transport management is also connected with the QCSP, as unloaded import containers have to be transported to the container yard and export containers have to be carried from the yard to the quay. To enable a high productivity of QCs, transport management is responsible for providing empty vehicles as soon as containers are unloaded and for delivering the right export containers from the yard such that they arrive at the quay on time.

Optimizing Gantry Crane Operations

Similar to QCs also, the gantry cranes are subjects of strategic and tactical management. Crucial decisions concern, for instance, the question of equipment selection, the intended degree of automation, and the yard layout design problem. Making these decisions is difficult for several reasons. The decisions to be made are highly interdependent and they are linked with high acquisition costs, and thus constitute a long-term basis for the operation of the container yard and the traffic facilities that build the hinterland interface. To utilize these infrastructures and equipment in the most profitable way is the subject of operations management. The operational problems met in the yard and the hinterland interface include crane deployment problems and scheduling problems for container storage and retrieval operations, which are described in the following subsections.

Yard Crane Deployment in Container Yards

The yard crane deployment problem (YCDP) is to decide which crane to work at which yard block in the course of time. The problem is most relevant for terminals where the number of yard blocks exceeds the number of available cranes. Such terminals often deploy RTGCs that can be moved flexibly from one-yard block to another. In contrast, RMGCs are bound by the rail infrastructure to one

particular block or to a line of blocks. In the latter case, crane deployment decisions can be relevant to some extent. The projected workload at each yard block serves as an input for crane deployment decisions. Assigning cranes to yard blocks typically has the objective of completing workload as fast as possible, or to shift as little uncompleted workload as possible into the next planning period. The planning horizon is usually set to a few hours. Therefore, the YCDP delivers a (dynamic) assignment of cranes to blocks, which is similar to the assignment of QCs to ships in the QCAP. A typical constraint in the YCDP is to assign at most one or two cranes to a container block at the same time in order to avoid increasing crane interference effects, which in turn reduce productivity. Furthermore, as the YCs available at a terminal can be heterogeneous, particular cranes might be unsuitable for operating in certain blocks. Like the QCAP, the YCDP is rarely investigated in the scientific literature as a problem on its own, but is often integrated with YC scheduling due to the strong interdependencies of both problems.

Gantry Crane Scheduling in Container Yards

The major task of operations management in the yard is to schedule stacking and retrieval operations of containers by YCs, which is referred to as the yard crane scheduling problem (YCSP). In this problem, a set of container operations (retrievals, stackings, repositionings) is given for a yard block, for which a service order needs to be determined together with a start time for each single operation. If multiple YCs are deployed to a block, it also needs to be decided which crane is to perform which operation. In contrast to the QCSP, there is no task aggregation applied in the YCSP, meaning that each container is treated as an individual operation to be scheduled. Relevant objectives are the minimization of a schedule's makespan and the minimization of earliness or lateness in completing operations (Wu et al., 2015). In the latter case, crane operations to be planned have a given due date which coordinates the YCs with the service processes at the seaside and the hinterland interface. Another objective of the YCSP aims at minimizing the effort of reshuffling containers. Reshuffling is necessary when stacked containers need to be removed in order to access a target container that is to be retrieved.

Standard constraints in a YCSP are to ensure that each operation is executed by a YC, where no YC can perform more than one container operation at a time. Scheduling is preemptive just like in the QCSP. Furthermore, precedence relations might be prescribed among operations to ensure that the YCs obey the loading sequences of the QCs and respect the stacking order of containers in the yard. Ready times might be given for stacking operations to respect the arrival times of transport vehicles at a block. Hard due dates can be given for time-critical retrieval operations. If two YCs operate simultaneously in a yard block, crane interference comes into play similar to the QCSP. For twin cranes, the non-crossing condition, as well as safety-distance requirements, has to be fulfilled (Gharehgozli et al., 2015). For dual cranes, it merely needs to be ensured that the cranes do not operate at the same yard bay at the same time. As a twin crane cannot reach every position in the yard block, a further constraint might be imposed for assigning container operations to specific cranes. In this case, an additional decision is to select a slot position where the container is handed over to the other crane, provided the container must be repositioned from one end of the block to the other.

It is evident that the YCSP is closely related to the YCDP. Hence, both problems can be solved together by a joint model. A related planning task results for an activity that is called "premarshalling." In this problem, containers are selected and repositioned in the yard in times of low workload. The idea is to provide better access (less reshuffling) when the service process of a ship starts, or when the time comes to move containers to/from trains or trucks. Repositioning operations are part of the job set in the YCSP. Further related planning tasks for the yard management are the allocation of storage slots to containers that are to be stacked, and the coordination of the crane operations with horizontal transport vehicles. Both of these decision fields impact YC operations, as they define parameters for storage/retrieval operations and impose operational constraints. Therefore, coupling storage slot allocation and horizontal vehicle scheduling with the YCSP improves the performance of the terminal subsystems. As horizontal transport operations are dynamic and volatile regarding vehicle arrival times, short-term planning and control, as well as online optimization of YC operations are important instruments too.

Gantry Crane Scheduling at the Hinterland Interface

Container terminals serve external trucks and trains that deliver export containers to the port and import containers to their destinations in the hinterland (Froyland et al., 2008). External trucks are often served directly at the yard block where the projected containers are located. Scheduling the service operation of external trucks is part of the YCSP in this case. Trains, however, are served in dedicated areas of a terminal that are equipped with their own gantry cranes. For these cranes, a scheduling problem has to be solved in order to sequence the loading and unloading process of containers to and from the trains. Similar to the YCSP, the objective is to achieve a fast handling of containers for a timely departure of trains.

The constraints are also similar to the YCSP: all operations have to be processed, due dates of containers or trains might be considered, and so on. As most rail systems do not allow for the stacking of containers on trains, direct access to every container is possible. Precedence relations can be of relevance if containers onboard a train have to be removed from their position before the loading of containers starts. As freight trains can be rather long, the shunting of trains might be required to reduce the travel effort of gantry cranes or to grant gantry cranes access to all parts of a train. This leads to a combined problem of gantry crane scheduling and train shunting, where a trade-off between train shunting and gantry crane movement must be sought.

Research Trends

In the paper, we have briefly discussed recent optimization approaches for operating the prevalent types of cranes met in container ports. There are, of course, many further topics and open questions in optimizing crane operations, which might create innovative and powerful planning models and methods in the future. New features coming up will be driven by technological progress (twin cranes, twin spreaders, indented berths), by experimental technologies (e.g., floating platforms for QCs at the waterside of a ship), or by advanced operational concepts (QC double cycling, direct ship-to-ship transshipment of containers, balancing of QC and YC workload). Even some issues of tremendous practical importance are not addressed sufficiently in the literature so far. One such example mentioned before is to ensure ship stability throughout the ship handling process, that is, when a QC schedule gets executed.

The optimization methods proposed to solve the planning problems described in this paper are quite similar to those in other scheduling problems like, for example, machine scheduling problems. Exact optimization based on mixed integer programming is, in the vast majority of cases, only applicable in relatively few instances. More advanced exact optimization techniques are not capable of substantially widening the range of solvability. Therefore, the development of tailored heuristics and, especially, of local-search-based metaheuristics has become a vital field of research. However, most studies propose methods for deterministic planning situations only, whereas few studies consider dynamics and uncertainty in crane operation processes. Such issues could be captured in terms of robust optimization or stochastic programming. As there are numerous sources of disturbances in the terminal environment (uncertain arrival times of ships and trains, breakdown of equipment, incomplete stowage plans or container data, uncertain handling times), it is of importance to support practice in coping with such challenges. More systematic comparisons are also required for the variety of models and methods proposed in these fields. This should help to consolidate knowledge and to identify those streams of research that are worth being further developed.

Finally, as was already mentioned in the previous sections, optimization problems for crane operations management have numerous interrelations among one another and also with other planning problems faced in container ports like, for example, berth planning. Although integration approaches have received some attention in the past, holistic concepts for a terminal-wide management of resources are still missing. An adjustment of a terminal's operations plans with external processes (e.g., arrival time planning for ships, trains, and trucks) can also be fruitful for achieving higher productivity and better service quality in the future.

Introduction

Liner shipping has been conveying cargoes to and from almost every place in the world and has become the major artery of world trade. In the process of economic globalization driven by containerization, liner shipping is the predominant service provider of containerized cargo transportation. Containerized trade volume in 2017 was 1.83 billion tons and accounts for 17% of global seaborne trade by weight, attaining up to 148 million twenty-foot equivalent units (TEUs). The liner shipping connectivity of a country measures its capacity to transport its containerized foreign trade by shipping companies and has a stronger impact on trade costs than the combined effects of logistics performance, air connectivity, costs of starting a business, and lower tariffs.

Compared to industrial shipping and tramp shipping, liner shipping is characterized by its fixed ship route and fixed schedule. The ships deployed on a liner service follow the same port rotation (itinerary). For instance, in service 1 illustrated in Fig. 1 (Wang and Meng, 2011), the deployed ships visit Hong Kong, Jakarta, and Singapore in sequence and then come back to Hong Kong again, which forms a loop. Thus, a service in liner shipping is also termed as *ship route*. The *service frequency* in liner shipping is usually weekly, with all the ships deployed on a service calling at a particular port on the same day of the week. This is the case especially for liner services connecting different countries, regions, and even continents. In the example illustrated in Fig. 1, two ships can be deployed on service 1, visiting Hong Kong every Friday, Jakarta every Friday, and Singapore every Monday. However, the feeder services serving a particular country or region generally adopt more diverse frequencies. For instance, the frequencies of the feeder services operated by Shanghai PanAsia Shipping Co. Ltd. vary from biweekly, through weekly to 2–7 visits per week to each port along a service route.

The costs of running a ship can be immense, consisting of (1) daily fixed operating costs (manning/crew costs, repair and maintenance, stores and lubricants, registration costs, management fees, etc.), (2) voyage costs (bunker fuel cost, port fees, canal dues, etc.), and (3) capital costs. From the perspective of the ship operations department of a shipping company, the operating costs of a ship only involve daily fixed operating costs and voyage costs, whereas capital costs are the concern of the financial department. Among these operating costs of the ship operations department, bunker fuel cost is the biggest single cost component: it typically represents more than 30% of the total operating cost; when the bunker fuel price is high, it can account for more than 50% of the total operating cost. The published balance sheet of Maersk Line show that a change in bunker fuel price (USD/ton) by several dollars would result in a tremendous change in its quarterly profit by several million dollars.

A liner container shipping company often operates a group of services over a number of ports to meet shipping demand and these services constitute a liner shipping *service network*. For instance, the service network shown in Fig. 1 is composed of three services. To give a more practical example, CMA CGM is operating around 500 container ships serving a global shipping network with more than 250 liner services. Without loss of generality, let us consider a service network that consists of a set of weekly services, denoted by $\mathcal{R}$, serving a group of ports, denoted by $\mathcal{P}$. For a particular service $r \in \mathcal{R}$, a port may be visited more than once by a container ship during a round trip of this service. Let m_r denote the number of ports of call on service $r \in \mathcal{R}$ and $p_r^i \in \mathcal{P}$ the corresponding i th port of call. The port rotation of service r can be expressed by:

$$p_r^1 \rightarrow p_r^2 \rightarrow \cdots \rightarrow p_r^{m_r} \rightarrow p_r^1 \quad (1)$$

Figure 1 A network with three liner services (ship routes). Source: Wang and Meng (2011).

Let $\mathcal{I}_r = \{1, 2, \dots, m_r\}$ be the set of indices of all port calls. We define $p_r^{m_r+1} = p_r^1$ indicating that the ship comes back to the first port of call after a round trip. The voyage between two consecutive ports of call p_r^i and p_r^{i+1} is called *leg i* of the service r . For instance, the three services shown in Fig. 1 can be respectively expressed as follows:

$$r = 1, m_r = 3 : p_r^1(\text{HK}) \rightarrow p_r^2(\text{JK}) \rightarrow p_r^{m_r}(\text{SG}) \rightarrow p_r^1(\text{HK}) \quad (2)$$

$$r = 2, m_r = 5 : p_r^1(\text{HK}) \rightarrow p_r^2(\text{XM}) \rightarrow p_r^3(\text{SG}) \rightarrow p_r^4(\text{CB}) \rightarrow p_r^{m_r}(\text{SG}) \rightarrow p_r^1(\text{HK}) \quad (3)$$

$$r = 3, m_r = 3 : p_r^1(\text{CB}) \rightarrow p_r^2(\text{CN}) \rightarrow p_r^{m_r}(\text{CC}) \rightarrow p_r^1(\text{CB}) \quad (4)$$

For the service 2, $\mathcal{I}_2 = \{1, 2, 3, 4, 5\}$. Its leg 2 is from Xiamen to Singapore, and leg 4 is from Colombo to Singapore. The notation p_r^i can easily differentiate these two port calls at Singapore: p_2^3 denotes the call at Singapore after Xiamen, while p_2^5 denotes the call after Colombo.

Container transshipment plays a paramount role in a modern liner shipping network, which allows containers to be discharged from a ship deployed over one service, stay in the transshipment port for some time, and then be loaded onto another ship deployed over the other service bound for their destination. Around 85% of containers arriving at Singapore are for the purpose of transshipment. In 2017, the transshipment cargo of Hong Kong accounted for 50.9% of its total port throughput. Transshipment enables a liner container shipping company to consolidate containers at a major port (transshipment hub) to improve the capacity utilization of its mega ships over trunk services. In the meantime, transshipment also expands the geographical coverage of a shipping company's service network because much more origin-destination (O-D) port pairs can be served owing to transshipment. For instance, in the shipping network illustrated by Fig. 1, there is no direct service from Xiamen to Chennai. However, we can transport the containers from Xiamen to Chennai by utilizing services 2 and 3 with transshipment at Colombo:

$$p_2^2(\text{XM}) \xrightarrow{\text{Service 2}} p_2^3(\text{SG}) \xrightarrow{\text{Service 2}} p_2^4(\text{CB}) \mapsto p_3^1(\text{CB}) \xrightarrow{\text{Service 3}} p_3^2(\text{CN}) \quad (5)$$

The optimal design of a liner shipping network is important for a shipping company, and it has also attracted considerable research efforts from academia. To design a shipping network, we need to determine the optimal ship route (port rotation) of each service, fleet deployment (type/capacity and the number of ships for each service), sailing speed of the ships over each service, and container flows through the whole network (i.e., over each sailing leg in the network), in order to meet transport demand and generate more profit. The liner shipping network design problem is quite computationally challenging, and the solution of its medium- and large-sized instances still requires further collaborative efforts of academics and industrial professionals.

Liner shipping network design is a strategic-level decision problem confronting a shipping company. However, it does not answer how all the services are synchronized to ensure smooth container transshipment operations among services. This will be addressed in the schedule design of liner shipping services, which provides a clear answer on the arrival time of the ships at each port of call of each service.

Schedule Design of Liner Shipping Services

Simply speaking, the scheduling of a liner shipping service means the determination of the arrival time of the ships at each port of call in the service. The first point that complicates this scheduling problem is the need to consider all the services in a shipping network simultaneously, since we must ensure smooth container transshipment operations among different services. Fig. 2 (Wang and

Figure 2 Schedules of service (ship route) 2 and service (ship route) 3. Source: Wang and Meng (2011).

Meng, 2011) illustrates a possible schedule design for services 2 and 3 in the example of Fig. 1. The ships over service 2 arrive at Colombo at 10:00 h on Tuesday, and the ships over service 3 arrive at Colombo at 00:00 h on Sunday. If we want to transfer some containers from service 2 to service 3 and fulfill the transshipment operations shown in Eq. (5), these containers have to stay at Colombo and wait for a ship over service 3 for around 4 days, which is undesirable. Thus, the first group of decision variables of this scheduling problem involves the arrival time of the ships at each port of call over each service of the whole network, denoted by $\{\phi_r^i | r \in \mathcal{R}, i \in \mathcal{I}_r\}$.

Sailing Speed Decision and Bunker Fuel Cost

The sailing speeds of the ships represent an essential factor in liner shipping schedule design, because sailing speed is the main determinant of a ship's fuel efficiency (i.e., daily bunker fuel consumption) and speed choice over each sailing leg will have an impact on the ship's bunker fuel consumption/cost. A *power law* is usually adopted to describe the impact of sailing speed v (knots) of a ship on its daily bunker fuel consumption Q (tons/day):

$$Q = a \times v^b \quad (6)$$

where the coefficients a and b can be calibrated based on historical data. When $b = 3$, the power law is also known as the *cubic law*. Fig. 3 (Wang and Meng, 2012a) provides some regression results over several container ships with the capacities varying from 3000 to 8000 TEUs, where the coefficient of determination R^2 is at least 0.96.

Assume that in each port of call i , a ship deployed on service r requires $\hat{t}_r^i$ units of time for queuing, pilotage in, mooring and unloading, and $\hat{t}_r^i$ units of time for loading and pilotage out of the port, then the sailing speed of the ships over leg i can be calculated later based on the schedule and its sailing distance l_r^i (nautical miles):

$$V_r^i = \frac{l_r^i}{\phi_r^{i+1} - (\phi_r^i + \hat{t}_r^i + \hat{t}_r^i)} \quad (7)$$

where V_r^i is in a technically feasible range $[\underline{v}_r, \bar{v}_r]$. Based on Eq. (6), the daily bunker fuel consumption of a ship over this leg is:

$$a \times (V_r^i)^b \quad (8)$$

Furthermore, the bunker fuel consumption of a ship over leg i is calculated as:

$$F_r^i = \frac{l_r^i}{V_r^i \times 24} \times a \times (V_r^i)^b = \frac{l_r^i \cdot a}{24} \times (V_r^i)^{b-1} \quad (9)$$

where "24" in the denominator converts the unit of sailing time from hours to days. We can see through Eqs. (7) to (9) that the schedule design of a liner service determines the ships' bunker fuel consumption. The bunker fuel cost can also be calculated given the bunker fuel price c^{fuel} (USD/ton).

Number of Ships and Schedule Tightness

The number of ships deployed in a service has a great impact on the ships' sailing speeds. Consider a liner service with three port calls. The time duration for a ship's dwelling at each port call is 24 h, and the total sea travel distance of a round trip is 6480 nautical miles. If we deploy three ships on this service, to maintain the weekly service frequency, the total trip time is 3 weeks $\times$ 7 days/week $\times$ 24 h/day = 504 h. The sea travel time, which is the difference between the total trip time and the port time, can be calculated as

Figure 3 Bunker consumption—sailing speed relation. Source: Wang and Meng (2012a).

$504 - (24 + 24 + 24) = 432$ h. Thus, the average sailing speed of the ships is $6480/432 = 15$ knots. Alternatively, if we deploy two ships on this service, the sailing speed to maintain the weekly service frequency is:

$$\frac{6480}{2 \times 7 \times 24 - (24 + 24 + 24)} \approx 25 \text{ knots} \quad (10)$$

Compared to the slow speed of 15 knots, sailing at 25 knots reduces the number of ships required to maintain the weekly frequency and saves the fixed operating costs such as crew costs, but significantly increases the bunker fuel consumption and cost. That is why most of the shipping companies are not willing to sail their ships at high speeds when the bunker fuel price is high. Instead, they adopt a *slow-steaming* policy by deploying more ships over their services. Sailing at a slow speed also means more *buffer*

time is built into the schedule of a service. When we experience port delays or bad weather at sea, we can take advantage of the sufficient buffer time, speed up and make up the time loss due to uncertainties or disruptions. In this sense, deploying more ships over a service will reduce the tightness in a service and enhance the robustness of its schedule. Therefore, the number of ships deployed over a service concerns the trade-off between fixed operating costs and bunker fuel cost, as well as the tightness and robustness of its schedule. The number of ships deployed over service r is denoted by N_r throughout this chapter. Moreover, we denote by c_r^{fix} the fixed operating cost associated with service r .

Container Routing Decision and Transit Time

Liner container shipping schedule design is also often interwoven together with container routing decisions. We denote by $\mathcal{P}_r = \{p_r^1, \dots, p_r^{m_r}\}$ all the ports of call in service r . To transport containers from port $o \in \mathcal{P}_r$ to port $d \in \mathcal{P}_s$, a transshipment operation must be conducted from service r to service s at a connected port $p_r^i = p_s^j$. In other words, the containers traverse through some legs on service r , arrive at the connected port, switch onto service s , traverse further on some legs of service s , and finally arrive at their destination $d \in \mathcal{P}_s$, which actually forms a *container route*. The transshipment involved in this container route is denoted by $\langle r, s, i, j \rangle$. For instance, Eq. (5) shows a container route from Xiamen to Chennai with a transshipment denoted by $\langle 2, 3, 4, 1 \rangle$. If the origin and destination ports are in the same service, a container route between them exists that does not involve any transshipment. For instance:

$$p_2^2(\text{XM}) \rightarrow p_2^3(\text{SG}) \rightarrow p_2^4(\text{CB}) \quad (11)$$

is a container route that only takes advantage of service 2. Two or more transshipment operations might be involved in a container route in practice, even though this is unfavorable. All the possible transshipment operations between services of the network are assumed to be given and denoted by a set:

$$\mathcal{T} = \{\langle r, s, i, j \rangle \mid r \in \mathcal{R}, s \in \mathcal{R} \setminus \{r\}, i \in \mathcal{P}_r, j \in \mathcal{P}_s, p_r^i = p_s^j\} \quad (12)$$

For the container flow for a specific O-D pair, there may exist several container routes serving it. Let us denote by $\mathcal{H}_{od}$ the set of container routes serving the O-D pair $\langle o, d \rangle$, with the shipment demand n_{od} , and define $\mathcal{H} = \bigcup_{o \in \mathcal{P}, d \in \mathcal{P}} \mathcal{H}_{od}$. Theoretically, the total number of container routes in $\mathcal{H}$ could be exceedingly significant. However, if some business rules apply, a set $\mathcal{H}$ of practical container routes will become constructible. For instance, a container route involved in a very long journey or involving transshipment at too many ports is considered as practically infeasible. We thus assume that the set $\mathcal{H}$ is also given. Two binary parameters σ_h^r and δ_h^{rsij} are additionally adopted, with $\sigma_h^r = 1$ indicating that container route $h \in \mathcal{H}$ contains leg i of service r , and $\delta_h^{rsij} = 1$ indicating that container route $h \in \mathcal{H}$ involves the transshipment operation $\langle r, s, i, j \rangle \in \mathcal{T}$.

Obviously, we can split the shipment demand n_{od} to different container routes $h \in \mathcal{H}_{od}$, and make a decision on the container flow Y_h through each container route $h \in \mathcal{H}_{od}$ (or equivalently the container flow X_r^i over each leg $i \in \mathcal{I}_r$ of service $r \in \mathcal{R}$, taking into account the capacity of the ship cap_r in number of TEUs). This is termed the *container routing decision*. The container routing decision influences the total port charge of all the containers (a part of voyage costs), because there is a unique port handling cost c_h^{port} (USD/TEU) associated with transporting one TEU along a particular container route h . For instance, for the container route shown in Eq. (5) from Xiamen to Chennai, the total port handling cost for one TEU is the sum of the loading cost at Xiamen, the transshipment cost at Colombo, and the discharge cost at Chennai. In the meantime, the container routing decision matters because different container routes have different *transit times* and transit times reflect the level of service (LoS) provided by a shipping company. In general, for a specific O-D, a shorter transit time is more attractive for shippers/freight forwarders. A shipping company is also willing to provide diverse transit times between a specific origin and destination for the choices of shippers, because a shorter transit time usually means a more expensive freight rate and shippers can choose the appropriate freight rate—transit time combination(s) based on their preferences.

The transit time along a container route consists of three components: the sailing time at sea, the port time, and the *connection time* (waiting time) of containers for transshipment from one service to another. From the perspective of the whole shipping network, the total time at sea and in port can be calculated based on the schedules of services and container flows:

$$\sum_{r \in \mathcal{R}} \sum_{i \in \mathcal{I}_r} X_r^i \cdot (\phi_r^{i+1} - \phi_r^i - \bar{t}_r^i + \bar{t}_r^{i+1}) \quad (13)$$

Consider the connection time for transshipment $\langle r, s, i, j \rangle \in \mathcal{T}$. If $\phi_r^i \leq \phi_s^j$, the containers in service r can be directly transshipped to service s after experiencing a waiting (connection) time of $\phi_s^j - \phi_r^i$ at the transshipment port. This is represented by the case where the auxiliary decision variable $\Lambda_{rs}^{ij} = 1$ in the model of the next section. Otherwise, the containers from a ship call on service r at time ϕ_r^i will be transshipped to a ship on service s arriving at the transshipment port at time $\phi_s^j + \Phi_{rs}^{ij} \cdot 168$ (168 h every week) such that:

$$\phi_s^j + (\Phi_{rs}^{ij} - 1) \cdot 168 < \phi_r^i \leq \phi_s^j + \Phi_{rs}^{ij} \cdot 168 \quad (14)$$

where $\Phi_{rs}^{ij} \in \mathbb{Z}^+$. Solving Eq. (14) yields:

$$\Phi_{rs}^{ij} = \left\lceil \frac{\phi_r^i - \phi_s^j}{168} \right\rceil \quad (15)$$

Thus, the connection time for this case is calculated as $\phi_s^j + \Phi_{rs}^{ij} \cdot 168 - \phi_r^i$. This is represented as the case where the auxiliary decision variable $\prod_{rs}^{ij} = 1$ in the model of the next section.

In summary, the scheduling of liner container services determines the number of ships deployed N_r , the schedule $\langle \phi_r^1, \phi_r^2, \dots, \phi_r^{m_r}, \phi_r^{m_r+1} \rangle$ of each service $r \in R$ (which also implies a decision on sailing speeds), and the container flow Y_h through each container route $h \in \mathcal{H}$, in order to achieve some predefined objectives, such as the minimization of the fixed operating cost and bunker fuel cost and of the total transit time of containers through the whole network.

A Base Mathematical Model for Schedule Design of Liner Shipping Services

Based on the earlier discussion, the schedule design problem of liner shipping services can be formulated as the mixed-integer nonlinear programming model as follows:

$$\min_{N_r, V_r^i, Y_h} \sum_{r \in R} c_r^{\text{fix}} N_r + c^{\text{fuel}} \sum_{r \in R} \sum_{i \in \mathcal{I}_r} \frac{l_r^i \cdot a}{24} (V_r^i)^{b-1} + \sum_{h \in \mathcal{H}} c_h^{\text{port}} Y_h \quad (16)$$

$$\begin{aligned} \min_{X_r^i, Y_h, \phi_r^i, \phi_r^{i+1}, \phi_s^j, \Phi_{rs}^{ij}} & \sum_{r \in R} \sum_{i \in \mathcal{I}_r} X_r^i \cdot (\phi_r^{i+1} - \phi_r^i - \tilde{t}_r^i + \tilde{t}_r^{i+1}) \\ & + \sum_{o \in \mathcal{P}} \sum_{d \in \mathcal{P}} \sum_{h \in \mathcal{H}_{od}} \sum_{\langle r, s, i, j \rangle \in \mathcal{T}} \delta_h^{rsij} \cdot Y_h \cdot (168 \Phi_{rs}^{ij} + \phi_s^j - \phi_r^i) \end{aligned} \quad (17)$$

subject to:

$$\phi_1^1 = 0 \quad (33)$$

The objective (16) minimizes the sum of the fixed operating cost, bunker cost, and port handling cost, while objective (17) minimizes the total transit time composed of sailing time, port time, and connection time for transshipment. The constraints (18–22) assist the calculation of connection time in the second term of the objective (17). Constraint (23) represents the relationship between the container flow of each sailing leg and the container flows over the container routes. Constraint (24) ensures that the container flow of each sailing leg of a service should not exceed its ship capacity. Constraints (25) and (26) calculate the sailing speed over each leg and impose a technically feasible range. Constraint (27) requires that the shipment demand for each O-D pair should be exactly met. Constraints (28–32) define the domains of decision variables. Constraint (33) breaks the symmetry of the feasible domain.

Liner Shipping Service Scheduling Under Uncertainties

Uncertainties and Their Impacts on Liner Shipping Service Scheduling

The on-time arrival of ships at each port of call is a key performance indicator of a liner service's reliability. SeaIntelligence reported that the schedule reliability of the world's top 15 container shipping companies in 2018 are all below 76%, and 3 of them maintained schedule reliability of below 70% (shippingwatch.com). In January of 2019, the on-time performance of the eastbound trans-Pacific trade liner services fell below 40%.

There are two types of uncertainties in container shipping transportation that have a great impact on schedule reliability (Li et al., 2016). The first type involves the regular uncertainties that occur frequently, such as port congestion, fluctuation of port handling productivity, and unexpected waiting time before port/channel entrance. It is possible to use probabilistic models to capture the realization patterns of these types of uncertainties. The second type represents a one-off uncertainty event that occurs occasionally and irregularly, such as bad weather, labor strikes, and port maintenance. The first type of uncertainty can usually be hedged against through buffers embedded in tactical-level plans/schedules, whereas the second type of uncertainty, also known as disruption events, needs greater managerial effort in the form of real-time recovery plans. In reality, there are often combinations of these two different types of uncertainties.

Schedule unreliability, caused by the inappropriate treatment of uncertainties, has a wide influence on the partners along the whole container shipping supply chain. First, the late arrival of ships or missed deliveries at ports will increase the inventory cost of shippers, and even lead disastrously to the stock-out of their products and/or product parts. The 2019 Trans-Pacific Maritime Conference in Long Beach witnessed the disappointment of shippers about the schedule unreliability of ocean carriers. Second, schedule unreliability also causes operational cost increases to shipping companies and container ports, such as a bunker cost increase due to speedups to make up sea time loss due to uncertainties, and port costs additionally incurred to deal with the ships that missed their schedules.

Addressing Uncertainties With a Proactive-and-Reactive Framework

A proactive-and-reactive planning framework can be adopted to address the uncertainties in liner shipping service scheduling. In the proactive planning phase, a robust tactical-level shipping schedule is targeted, which is capable of absorbing regular uncertainties and provides a hedge against the possibility of bad weather at sea (sea contingency). The robustness of the schedule can be developed by introducing a certain amount of *buffer time* (slackness) that can be regarded as the additional time included in the timetable on top of the minimum required tour time. Most existing studies on liner shipping service scheduling under uncertainties have addressed how to build the appropriate amount of buffer time into a tactical-level shipping schedule of a service (Wang and Meng, 2012b). Robust liner shipping service scheduling usually considers the arrival time at each port and the number of ships deployed as the decision variables, because the number of ships together with sailing speed determines the tightness of the schedule (buffer time). Sailing speed adjustment is often considered as the recourse action for any sailing delays. The optimization objective includes the fixed operating costs, the expected bunker fuel cost under uncertainties, and the delay handling cost.

In the reactive phase, an operational-level recovery plan is targeted which provides the shipping company with optimal recourse actions after uncertainties occur. The uncertainties here can be either or both of regular and one-off uncertainty events. The recourse actions include changing sailing speed, skipping a port call, swapping two port calls, and even a cut-and-go action which stops the handling of containers at a port and allows the ship to depart immediately. The objective of an operational-level recovery plan is to enable the ships to recover from these uncertainties affecting defined schedules as soon as possible and at the least cost.

Some existing studies also take advantage of two phases to build a robust sailing schedule, where the first phase builds optimal buffer time and the second phase assesses the performance of the buffer time through recourse actions when uncertainties actually happen. Many practical considerations have also been addressed by existing studies, such as the impact of the dam lock system along a river, and the influence of the traffic convoy system and toll pricing policy of the Suez Canal.

Main Solution Methodologies

As the first resort, the state-of-the-art commercial optimization solvers, such as IBM ILOG CPLEX Optimizer and Gurobi, can be utilized to solve these scheduling models if the built models can be cast as a mixed-integer linear programming model, mixed-integer quadratic programming model (with linear and/or quadratic constraints), and even mixed-integer bilinear programming model. As

an example, the nonlinearity caused by the bunker fuel calculation in Eq. (9) can be addressed by second-order cone programming or outer approximation with linear constraints, and then CPLEX is used. Sometimes, it is also possible to design tailored cutting planes. When the impact of payload on the fuel consumption rate is additionally considered (as in the well-known *Admiralty coefficient*), nonconvexity will be created in models. In this case, the spatial branch-and-bound algorithm can be adopted which is able to produce epsilon-optimal solutions. Dynamic programming and time-space network models are also widely adopted to solve the liner shipping service scheduling problem.

As far as robust schedule design under uncertainties is concerned, stochastic programming models can be adopted to capture both here-and-now and wait-and-see decision variables. Sampling average approximation techniques are also helpful in estimating the expected values of random variables. Existing studies have also developed some stochastic dynamic programming and stochastic optimal control models for robust shipping schedules and operational recovery plans.

Future Research Opportunities

The schedule design for a liner shipping network with diverse service frequencies needs more research effort. Nowadays, global shipping routes basically adopt weekly liner services because of inertia, possible production and selling rhythms of shippers, and

Figure 4 Relationship between ship displacement, cargo weight, and ballast water. (A) Displacement and weights of cargo, ballast water, and bunker fuel of a 14,000-TEU container ship (Ship S1) in service of 271 days. (B) Estimating the displacement of a 14,000-TEU container ship (Ship S1) with cargo weight. (C) Displacement and weights of cargo, ballast water, and bunker fuel of a 9,400-TEU container ship (Ship S2) in service of 301 days. (D) Estimating the displacement of a 9,400-TEU container ship (Ship S2) with cargo weight.

remarkable difficulty in reconfiguring the whole shipping network and synchronizing intercontinental and regional/feeder services. This motivates researchers to conduct their studies mainly in the context of weekly service frequencies. However, diverse frequencies should be further considered in future for two reasons. First, no theoretical fundamentals exist that prevent the shipping companies from introducing non-weekly services in the main trade routes in future. Second, the frequencies of feeder services are quite diverse in reality (for instance, biweekly, weekly, 5 days, 2.5 days, etc.). It would be interesting to study the schedule design problem for a shipping network with diverse frequencies and investigate the benefits of changing the frequencies (Du et al., 2017).

Ship payload is also widely ignored in existing studies, even though it has an impact on the daily bunker fuel consumption of a ship. Few studies consider this in a simple form, for example, the Admiralty coefficient, in ship routing and scheduling problems. However, in practice, the influence of weather and sea conditions on a ship's fuel efficiency might exceed that of its payload. In the meantime, directly adopting cargo load as the proxy of a ship's displacement may not be reliable, because ballast water is also a significant part of a container ship's displacement (Fig. 4). It would be intriguing to investigate, with tangible industry data support, how a ship's payload and cargo/container routing influence the bunker fuel cost in a shipping service network.

Designing the schedules for a liner shipping service network also requires more data-driven studies, through collaboration with industry partners. For instance, researchers are encouraged to conduct empirical studies on the buffer times involved in the service schedules of their industry partners based on real data, and further investigate their performance in enhancing the robustness of schedules. Historical data accumulated in shipping companies and other organizations, such as voyage report data and weather archive data, can also be adopted to model the synergetic influence of sailing speed, displacement, trim, and weather and sea conditions on ship fuel efficiency (Du et al., 2019). In the meantime, the state-of-the-art robust optimization theories developed in the past decade (Bertsimas et al., 2018; Wiesemann et al., 2014) provide advanced methodologies to deal with uncertainties in different ways, such as distributionally free robust optimization, which is promising in introducing greater insights into liner shipping schedule design with different types of uncertainties.

Introduction

Dry ports fulfill a defined role in the development of port and hinterland systems and comply with specific functions within the multiplicity of types of inland facilities serving the logistics and transport industry. Thus it is relevant to understand their specific role from both spatio-temporal and institutional perspectives, particularly their position within the port life cycle. Given the multifarious features and concepts found in previous discussions of inland facilities in the literature, it seems necessary to clearly differentiate the dry port from other types of inland freight facilities and identify its role from a systems perspective.

Toward a Contemporary Definition of Dry Ports

The original dry port concept dates back to 1982 and emerged with the expansion of global trade and the advancement of containerization, allowing through bills of lading and directly connecting inland regions. This dry port concept was defined as “an inland terminal to which shipping companies issue their own import bills of lading for import cargoes, assuming full responsibility of costs and conditions and from which shipping companies issue their own bills of lading for export cargoes” (UNCTAD, 1982).

Beresford and Dubey (1991) argued that dry ports and inland clearance depots (ICDs) were functionally synonymous, as the focus of such facilities was to enable customs clearance at distant inland locations, particularly but not exclusively for the benefit of landlocked countries not possessing their own seaports. Nevertheless, despite the clear maritime role played by dry ports from their inception, early dry ports were generally developed by inland actors, a requirement emerging from being landlocked or otherwise suffering from poor port access. While access to rail or inland waterway transport was considered desirable, in these early discussions the transport mode was not prescribed, as the most important contribution of the dry port facility was to improve the flow of international trade for less accessible regions by saving time, delays and fees in the port, with the potential for other related services, such as intermediate storage, processing and repacking, enabling greater consolidation of shipments. While the focus in developed countries tends to be on the usage of dry ports for high volume container shuttles (see below), in developing countries where customs clearance at a seaport can take several days, customs reform is ongoing and this activity remains one of the key reasons for passing containers through a dry port, even if using road transport. For example, a study of 18 dry ports in China by Monios and Wang (2013) found that seven were rail-connected and three had rail connections nearby, while eight used road transport under customs bond to connect to seaports.

In short, a dry port is “a location in the interior of a country that fulfils original port functions” (Cullinane and Wilmsmeier, 2011). Considering that dry ports should fulfill such original port functions, they need to comply with specific infrastructure and services and must be established as a common user facility, accessible to all shippers, whether operated under a public, private or mixed model. Beresford and Dubey (1991) stressed in relation to the latter that any exclusivity in the access would defy the original idea of a dry port, a distinction that has received little attention by later authors.

Beyond the “original port functions”, the dry port concept by definition includes the type and characteristics of accessibility and interlinkage with the seaport. This high-level accessibility is related to the “main street” concept outlined by Taaffe et al. (1963), who argued that certain inland destinations will create *Bedeutungsüberschuss* due to high-priority linkages toward the seaports. In their conceptualization of port rationalization, Notteboom and Rodrigue (2005) characterize inland terminals (without defining dry ports specifically) as active nodes in shaping the logistics and transport chains in the context of linkages between ports and their hinterlands.

In the 37 years since the first definition of dry ports, the discussions and related research topics on the concept have clearly evolved (Wilmsmeier and Monios, 2020; Witte et al., 2019). Nevertheless, this evolution has been accompanied by a process

Table 1 Dry port development matrix

Phase	Development	Introduction	Operation	Extension strategy
Direction	Inside-Out	Inside-Out	Inside-Out	Inside-Out
	Outside-In	Outside-In	Outside-In	Outside-In
	Bi-directional	Bi-directional	Bi-directional	Bi-directional
	Inland only	Inland only	Inland only	Inland only

Source: The data is based on the intermodal terminal life cycle (Monios and Bergqvist, 2016) and the directional model (Wilmsmeier et al., 2011).

of vagueness in the definition of dry ports and related concepts of inland terminals or inland ports in the literature (Beresford, 2009; Cardebring and Warnecke, 1995; Jaržemskis and Vasiliauskas, 2007; Lévêque and Roso, 2002; Roso et al., 2009; UN ECE, 1998; UNESCAP, 2009). During this wave of dry port studies, where a large growth in containerized transport through ports in developed countries has led to modal shift and port congestion rising up the policy agenda, dry ports are more likely to be connected to seaports by high capacity transport modes such as rail and inland waterway. Thus the definition provided by Lévêque and Roso (2002), is that a dry port is “an inland intermodal terminal directly connected to seaport(s) with high capacity transport mean(s), where customers can leave/pick up their standardized units as if directly to a seaport.” Under this conceptualization, the role of the seaport is also foregrounded, whereby Roso et al. (2009) state that “for a fully developed dry port concept the seaport or shipping companies control the rail operations.” This emerging duality between inland and seaport actors controlling the dry port system was conceptualized in the directional model of Wilmsmeier et al. (2011) discussed in the following section.

Thus two primary axes of dry port concepts can be identified: on the one hand an ICD where the role of customs and an inland-specified bill of lading are dominant, and on the other an intermodal terminal providing access to intermodal transport for high-capacity port flows. While both definitions recommend the provision of supporting logistics activities at the dry port, this third axis of the dry port concept has become more relevant considering recent advances in logistics and the increasing complexity of the port-hinterland system. Such evolution raises the importance and desirability of colocating a dry port with some kind of logistics platform or freight village (Rodrigue et al., 2010; Monios, 2015). A modern or full-service dry port could be expected, therefore, to be a larger facility including supporting logistics activities either onsite or close nearby. Rodrigue et al. (2010) drew a useful distinction between the transport function (classifying them as satellite terminals, transmodal centers, and load centers) and the supply chain function (i. e., the level of logistics or value-added activities performed onsite or nearby). This functional approach is somewhat similar to the close, mid-range and distant dry port model presented by Roso et al. (2009) and the later sea port-based, city-based and border-based model proposed by Beresford et al. (2011). It could be argued that this kind of functional approach, based on the usage of each node, has more utility than overall terms such as “dry port” or “inland port.” It allows a research agenda to be developed along the lines of the purpose and usage of these nodes in the transport chains that they shape.

Dry Ports in the Port Development Cycle

Dry ports provide a means both to improve the accessibility of an inland location and to expand the influence of a seaport in its respective hinterland. Thus the dry port concept stands next to, and is complementary to, different types of inland terminals and any discussion cannot be separated from the evolution of ports, port hinterland systems, and the logistics sector.

Cullinane and Wilmsmeier (2011) and Wilmsmeier and Monios (2020) argue that the dry port concept is one of the possibilities in the extension of a port life cycle, when a port or port system has reached the maturity phase. A port in its maturity phase suffers from limitations in its physical expansion, due to its traditional location (often close to a city centers). These limitations are usually paired with negative externalities, such as congestion, air pollution or noise, affecting the proximity of the port and port city, a major driver being port-related freight transport. Cullinane and Wilmsmeier (2011) argued that rationalization efforts of port services, as well as process innovations and feasible investment primarily aimed at capacity effects (e.g., conversion to more effective storage technologies), will reach their limits. Consequently, a dry port development allows the possibility of “location splitting” (Schaezel, 1996), whether at short, medium or long distance to the seaport, and can create positive expansion effects. This development can enhance the flexibility and the adaptability of the port-hinterland system, release pressure on the traditional port setting and support the improvement of its environmental performance. However, it can also require adjustments in the regulatory and institutional environment, as the roles and activities of key actors in this system are transformed (van den Berg et al., 2012). The anticipated development should not only create new system capacities and alleviate negative external effects, but also needs to comply with the previously defined common user access. Further, dry port development may affect traditional hinterland competition patterns, as this development will significantly alter the hinterland of the respective port(s).

Wilmsmeier et al. (2011) argued, however, that dry port development is not always initiated as a result of a limitation or crisis in the seaport system, thus introducing the directional development perspective. This approach combines both first and second wave dry port definitions, according to which dry ports may be developed by inland or seaport actors, respectively. The directional model

helps to accentuate the challenges of port-hinterland integration and the potential conflicts between different actors. Inside out development strategies (land-driven, e.g., developed by rail operators or public bodies) can be contrasted with those that are pursued outside in (sea-driven, e.g., developed by port authorities or port terminal operators). In response to recent empirical research depicting different permutations around these two broad directions, such as bidirectional developments (Bask et al., 2014; Raimbault et al., 2016), as well as to better reflect the life cycle of both ports and inland facilities (Monios and Bergqvist, 2016), Wilmsmeier and Monios (2020) refined the directional model to account for a four-phase dry port development via-à-vis seaports: inside out, outside in, bidirectional, and no seaport involvement (Table 1). According to a recent review of publication trends on the topic, Witte et al. (2019) found that the implementation of the directional model defines what they refer to as the contextualization stage (2012–17) in inland/dry port research.

Examples of outside in development, driven from the seaward side, are Rotterdam sea port terminal operator ECT vertically integrating inland through the purchase of terminals at Venlo, Willebroek, and Duisburg (Veenstra et al., 2011), Virginia Inland Port developed by the port of Virginia, United States (Roso and Lumsden, 2009) and the Terminal Intermodal Logístico Hidalgo, located 50 km north of Mexico City and connected to the Port of Veracruz (Wilmsmeier et al., 2015). A public sector alternative is demonstrated in Spain where, for example, port authorities such as Barcelona are investing in inland terminals in the Spanish hinterland (e.g., Madrid/Coslada, Azuqueca de Henares, and Zaragoza) (Monios, 2011). The ECT example shows how a private sector company can expand its industry position through integration strategies, while the Spanish case demonstrates the use of joint ventures between public and private bodies to achieve a common goal, both being developed outside in.

Inside out developments can be quite diverse and do not always conform explicitly to one dry port definition. One example is freight villages developed by regional organizations in Italy, which can be characterized as colocated intermodal terminals and logistics platforms with customs facilities connected to ports (Monios, 2016; Monios and Wilmsmeier, 2013). Another is the Rickenbacker inland intermodal terminal in Columbus, Ohio, developed by rail operator Norfolk Southern and linked to the port of Virginia through the Heartland Corridor (Monios and Lambert, 2013). Smaller developments include several dry ports in Sweden connected to the Port of Gothenburg (Bergqvist and Woxenius, 2011). Each of these examples has been developed through different business models and leading actors range from cities to regions to rail operators to logistics providers (Bergqvist et al., 2010; Monios, 2015).

While not all site development strategies can be classified solely as one or the other, this broad conceptual distinction highlights conflicting strategies and the importance of port investment if a dry port development is to lead to a successful business, handling port container shuttles for one or more seaports (Monios and Wilmsmeier, 2012). Furthermore, there has been some debate concerning whether outside in or inside out development is the most likely model in developed or developing countries (Monios and Wilmsmeier, 2012; Monios and Wang, 2013; Ng and Cetin, 2012). It can be expected that the growing geographical coverage on port hinterland integration concepts in general and the analysis of dry ports in different geographical settings will give the opportunity to compare characteristics, factors of success or failure, as well as institutional settings.

This directional model highlights that the assumed levels of hinterland integration are accompanied by difficulties arising from the nature of creating intermodal transport corridors. The actual development and integration of such transport corridors, whether developed by ports (outside in) or by inland actors (inside out), faces significant challenges; since changing the participation of rail from a marginal share in hinterland transport requires the implementation of long-term strategies and sometimes modal shift policies. Such a major industrial shift can be difficult when the transport industry remains fragmented, large shippers refuse consolidation, and government subsidies to shift traffic to rail are fragile. At the same time, dry ports change the competition in the hinterland and the potential capture and control of inland transport networks require public sector regulation in order to prevent potential monopolization or market power (particularly given the continuing vertical integration in the shipping and port sectors).

Moreover, in many cases, the complexity of institutional design, conflicts of interest and collective action problems continue to constrain integration between maritime and inland transport systems. For example, the level of operational integration between an inland freight facility and a port (either solely through joint activities or, more formally, through ownership) can influence how daily operational issues and contractual problems between rail operators serving the dry port would be resolved (Bergqvist and Monios, 2014). Which party takes responsibility for such complexity is directly related to the institutional relationships between the various organizations (e.g., whether the port authority or port terminal operator owns the dry port, whether they own or have any integration with the rail shuttles or whether the relationship is handled through third-party contracts—Monios, 2015). Accordingly, development decisions need to be based on an analysis of whether implementing a dry port is simply a protectionist measure that would prop up a failing seaport or whether it will be planned as a node within an integrated seaport hinterland system (as argued by Cullinane and Wilmsmeier, 2011).

Emerging Key Questions

While many studies relate to the potential and development of dry ports and advance the theoretical and conceptual discussion, the question remains whether dry port development has a long-term positive effect on the performance and sustainability of logistics systems (Awad-Nunez et al., 2016). The majority of research argues for positive environmental effects of dry ports on hinterland logistics, originating from the shift toward the use of high-volume transport modes (rail or inland waterway) to connect the seaport and the dry port (Hanaoka and Regmi, 2011; Lättilä et al., 2013; Tsao and Linh, 2018). This originates from the fact that dry port development encourages investment in railway or inland waterway infrastructure to create the basis of high-volume flows (Bergqvist

et al., 2015). A shift of modes can bring significant reductions in externalities, such as alleviating road transport congestion and accidents in proximity to seaports (Fazi and Roodbergen, 2018; Gonzalez-Aregall and Bergqvist, 2019; Hanaoka and Regmi, 2011), and to reduce GHG emissions due to the better environmental performance of rail or inland shipping in comparison to road freight transport. However, the calculation of emissions reductions should not be limited to the seaport-dry port corridor, but should take the overall emissions of the whole logistics chain being served in the port hinterland production system.

Further, as derived from the port life cycle, research argues that the successful implementation of a dry port, beyond alleviating congestion, will reduce capacity limitations of storage space and operations in the port(s). A particularly relevant concept in this context is the extended gate, discussed by Rodrigue and Notteboom (2009), van Klink and van den Berg (1998), and Veenstra et al. (2011) that has been considered an example of outside-in integration as mentioned earlier. The concept of “terminal haulage” (as opposed to carrier or merchant haulage), represents a new stage of integration that could hold significant potential if technical and operational obstacles can be overcome. The extended gate terminal haulage concept can also be related to a move from push logistics toward pull logistics or even “hold logistics”, as outlined by Rodrigue and Notteboom (2009) in their concept of supply chain terminalization, whereby inland terminals are actively used to manage inventory flows.

This discussion of managing hinterland flows between the seaport and dry port emerges from the development proposal stage and remains key throughout the life of the facility. A dry port may be developed under certain assumptions about its business model and traffic sources, with particular expectations of the role it will play in the port’s ongoing strategic development (e.g., will the port guarantee traffic levels, will the port and dry port collaborate in organizing rail shuttles or will it be left to the decision of rail operators). But over the years of its operational life, the conditions may change and with that the role of the dry port (Monios and Bergqvist, 2016). The dry port may be sold or reconcessioned, it may gain or lose the business of various rail operators or even ports and it may require maintenance or upgrades and become involved in contractual disputes over who should fund these investments. Thus the governance arrangements and business model for the dry port are closely linked to its relationship with the seaport and their separate, but linked, life cycles (Table 1).

Conclusion and Research Agenda

In the evolution towards more sustainable transport systems, effective port hinterland integration is a key element and dry ports are one option. The aforementioned discussion reveals the system complexity when including the hinterland and its elements (especially the dry port) in the port life cycle perspective. The expansion and evolution of the dry port concept is intrinsically linked to capacity and structural changes, as well as to vertical integration, all of which increase both the complexity of systems and the potential price of errors or dysfunctionalities in the system. Thus key strategic questions remain, which provide an agenda for future research. Why, when and how should a seaport invest in a dry port? What kind of business model is most suitable for the dry port? How are governance and institutional issues managed between the various inland and seaport actors? Finally, regarding all three questions, how do these change over time?

Introduction

Arctic shipping includes shipping activities occurring north of the Arctic Circle or in seasonally ice-covered regions south of the Circle for the entirety or part of their voyage. Historically, Arctic shipping has been confined to the summer season, when vessels could operate without the threat of sea ice or would only have to deal with remnant melting ice floes. This limited Arctic shipping activity to areas such as the Baltic, Bering, Barents, and southern Chukchi and Beaufort Seas, along with Hudson and Baffin Bay. However, with declining sea ice extent, trans-Arctic routes have attracted much attention and become a reality. The Northern Sea Route (NSR) has become well traveled during the open water season, connecting Europe and Asia via a trans-Arctic route through the marginal Sea of the Russian Arctic. On the North American side of the Arctic, the Northwest Passage (NWP) through the Canadian Arctic Archipelago has become increasingly open and, while several successful transits have occurred, sea ice does remain a threat from year to year along the narrow passages. Finally, a true Trans-Polar Route (TSR) connecting Europe and Asia has been forecast to become a viable shipping route as the areal extent of Arctic sea ice continues to decline into the coming decades. These routes are shorter than conventional routes via major canals and are becoming more viable as the number of ice-free days during summer continues to increase. Furthermore, the reduction in sea ice extent increases the accessibility to known resources in both the terrestrial and marine areas of the Arctic. Unsurprisingly, both Arctic and non-Arctic countries have shown substantial interest in how Arctic shipping should be developed. For example, calling itself a “near-Arctic state,” in 2018, China has included the Arctic into its Belt and Road Initiatives (BRI) (in the form of 2.0 BRI) through its “Polar Silk Road” policy. However, the feasibility and economic viability of these Arctic routes are still under intense debate, while issues pertaining to Arctic sovereignty and environmental protection are paramount. Key controversial points include the extent of genuine interest in Arctic shipping—whether shipping stakeholders treat Arctic shipping routes as serious alternatives, as well as the unclear environmental and socioeconomic impacts that Arctic shipping would pose, especially in places with a lack/shortage of infrastructural support or emergency response capacity.

Actors in the Arctic

Due to geography and different understandings of maritime boundaries, the governance of the Arctic marine environment is the subject of great debate. Within the Arctic, the Arctic Council is an intergovernmental forum that promotes cooperation, coordination, and interaction among Arctic countries and Arctic indigenous groups on economic, social, and environmental issues. It

Actors in Arctic geopolitics

Figure 1 The major actors in Arctic geopolitics.

comprises eight member states: Canada, the Kingdom of Denmark, Finland, Iceland, Norway, the Russian Federation, Sweden, and the United States; six indigenous organizations: the Aleut International Association, the Arctic Athabaskan Council, Gwich'in Council International, the Inuit Circumpolar Council, Russian Association of Indigenous Peoples of the North, and the Saami Council; as well as other non-Arctic countries that are granted observer status such as China, India, Japan, and others (Fig. 1). Arctic Council observers primarily contribute through their engagement in the Council at the level of working groups: Arctic Contaminants Action Program (ACAP), Arctic Monitoring and Assessment Program (AMAP), Conservation of Arctic Flora and Fauna Working Group (CAFF), Emergency Prevention, Preparedness and Response Working Group (EPPR), Protection of the Arctic Marine Environment (PAME), and the Sustainable Development Working Group (SDWG). In this case, Arctic countries cooperate closely to address common challenges and solve territorial disputes by diplomatic approaches. However, the more attention the Arctic gets on the international agenda, the more the Arctic becomes an arena for strategic rivalry. Possible tension between Russia and NATO or United Nations Security Council (UNSC) Allies, as well as China's increasing engagement, could lead to a more complicated political environment regarding development in the Arctic. The United Nations Convention on the Law of the Sea (UNCLOS) is the international agreement with respect to the use of the world's oceans, establishing guidelines for businesses, the environment, and the management of marine natural resources. The UNSC is one of the six principal organs of the United Nations (UN), ensuring international peace and security. Permanent members include China, France, Russia, the United Kingdom, and the United States. NATO (the North Atlantic Treaty Organization) is an international alliance, established at the signing of the North Atlantic Treaty.

The Physical Aspects: The Arctic Marine Environment Under the Influence of Climate Change

In its Fifth Assessment Report (AR5), the Intergovernmental Panel on Climate Change (IPCC) estimated, with high confidence, that between 1880 and 2012 the global mean temperature increased roughly 0.85° C (IPCC, 2013). Moreover, temperatures in the Polar regions have increased at a significantly greater rate than the lower latitudes, due to a number of mechanisms collectively referred to as "Polar Amplification" (ACIA, 2005; Stocker, 2014). Warming temperatures in the Arctic have driven a rapid decline in sea ice over the last 50 years and have triggered changes in Arctic weather systems (IPCC, 2013), with considerable implications for marine transportation.

Sea Ice

Sea ice is a complex and dynamic medium that forms from freezing seawater and presents the greatest physical constraint on Arctic shipping. It is not only important to know where the ice is present and how much of it is there, but also what type of ice is present and how thick it is, if it is mobile and if there are hazards such as large ridges or icebergs present within the ice cover. Given the remoteness of the Arctic, information on the ice cover in a particular region is typically provided by satellite-based

Figure 2 The 1981–2010 average maximum (March) and minimum (September) sea ice extent. Note: The three trans-Arctic shipping routes have been overlaid. Source: Data from the National Snow and Ice Data Center.

observations. National ice services present information on sea ice concentration and type in the form of regional ice charts that utilize the Egg Code of the World Meteorological Organizations (WMO). The Egg Code is a standardized method for representing sea ice concentration (in tenths), stage of development and motion, and indicates the presence of heavily deformed ice or icebergs for a particular region with standardized colors and numeric codes. Sea ice concentration describes the percent coverage of sea ice within an area with the ice edge typically being defined at the 15% (or one-tenth) contour. Sea ice type describes the stage of development of the ice cover, which can range from new thin seasonal ice to thick deformed multiyear ice. While observations of ice thickness are typically limited, ice thickness corresponds to ice type, which can therefore be used to infer the thickness and strength of ice cover in a particular area. Sea ice is characterized by a pronounced annual cycle from a maximum extent and thickness in late winter (March to April) to minimal extent and thickness at the end of the summer melt season (September) prior to the onset of fall freeze-up. At its maximum extent, there is approximately 14 million km² of sea ice in the northern hemisphere, with sea ice completely covering the Arctic Ocean and peripheral Seas like the Bering Sea and Sea of Okhotsk on the Pacific side, Hudson Bay in central Canada, and Baffin Bay and the Greenland and Barents Seas on the Atlantic side. Conversely, during the September sea ice minimum the ice cover retreats from the southern marginal seas toward the central Arctic (Fig. 2). Historically, the ice cover declined to around 7 million km², presenting open water conditions in a narrow coastal fringe around the central Arctic Ocean. However, since routine satellite observations of the ice cover began in 1978 there has been a significant decline in monthly sea ice extent during all months. This negative trend is most pronounced during summer when processes like the ice-albedo feedback loop amplify ice melt. Increasing temperatures combined with feedback cycles has reduced the average September ice extent to 4.54 million km² over the last decade, with a record minimum extent of 3.39 million km² in 2012. Reduced sea ice extent has occurred concomitantly with a decline in sea ice thickness and a transition from an older, thicker resilient ice cover to a younger, thinner, more mobile ice cover prone to enhanced ice melt. Global climate models project that this change will continue into the future, with the Arctic one day becoming ice-free. But while projecting the exact occurrence of an ice-free Arctic is inexact, the models do show continued trends toward progressively longer open water periods along both the NWP and the NSR and eventually the recurrence of open water along a transpolar sea route over the TSR. Underlying these trends, it is important to note that sea ice maintains a high degree of interannual variability, so routes that may

be ice-free one year may remain ice covered the next year. Such has been the case along the NWP during recent years as the ice cover within the Canadian Arctic remains a complex dynamic feature that still maintains thick multiyear sea ice that is able to persist through summer.

While the declining ice cover has attracted attention to Arctic sea routes, the fact is that sea ice continues to pose a threat to vessels operating in the Arctic. These vessels can either avoid sea ice by confining their activities to the seasonal open water periods in certain Arctic regions, or they can operate within the ice cover using an appropriately ice strengthened vessel. Operating during the open water period is feasible for southern areas that reliably become ice-free every summer, such as the Bering, Baltic and Barents Seas, Hudson Bay, and a majority of Baffin Bay. However, open water periods may be too short, or interannual variability in the ice cover may not reliably present ice-free conditions along certain routes. Hence, vessels operating in the Arctic typically have some measure of ice-strengthening or ice-breaking capability to contend with the risk of ice along their route. A vessel's degree of ice strengthening reflects its design (e.g., hull strength and thickness) and power. The world's shipping fleet contains a broad range of ice-strengthened vessels, varying from "Open Water" (OW) vessels capable of traveling in ice up to 15 cm thick to "Polar Class" vessels that are capable of breaking the ice and can therefore operate in ice up to several meters thick ([Transport Canada, 2010](#)). In recent decades, vessels are built according to numerous different ice-capacity classification systems, resulting in a patchwork of vessel designs and regulations ([Canadian Coast Guard, 2012](#); [Government of Canada, 1985](#)). However, with regard to ice-strengthened vessels, it is now recommended that new vessels be built according to international guidelines set out in the *Requirements Concerning Polar Class* by the International Association of Classification Societies (IACS) at the behest of the International Maritime Organization (IMO) ([International Association of Classification Societies, 2011](#); [Transport Canada, 2009](#)). Ice-strengthened vessels designed according to an earlier classification system may apply for an equivalency in the IACS system.

Arctic Weather

While sea ice is the main determinant of Arctic marine accessibility, the weather along shipping routes is a concern and has garnered far less research attention. Historically, in situ weather observations from the Arctic are limited, particularly within the marine environment, where observations are limited to a few ice camps and ship-based studies. However, the advent of autonomous drifting platforms and satellite remote sensing has improved the observational and forecasting capabilities over the Arctic marine environment. Events such as storms that increase winds and waves can be particularly dangerous in areas of the Arctic where seafloor mapping, infrastructure, and emergency response capacity can all be limited. Under a changing climate, the Arctic is expected to experience more storms, particularly during the summer when a majority of vessels operate in the Arctic. Additionally, the reduction in sea ice extent is increasing fetch and therefore promoting wavier conditions within Arctic waters ([Thomson and Rogers, 2014](#)). While vessels contend with waves in all waterways, increasing wave activity can make navigation through narrow poorly charted channels, particularly along the NWP, more hazardous. Perhaps the greater impact of a wavier Arctic Ocean will occur on coastal infrastructure that is both limited in presence and capacity and may be compromised by coastal erosion.

An issue that is unique to Arctic shipping is the potential for the accumulation of ice on the vessel from rain, sleet, snow, and fog or sea spray in near freezing temperatures. Ice accumulation impacts the balance and stability of a vessel and may create hazardous conditions for vessels operating late into the open-water shipping season or through winter when temperatures are hovering near, or well below the freezing point.

The Socioeconomic Aspects

The Opening of Shorter Shipping Routes

With climate change driving considerable changes in the Arctic, previously impeded routes are now opening, offering the potential to connect international markets across shorter polar routes ([Lasserre and Pelletier, 2011](#)). For instance, the Arctic route can cut the Rotterdam-Seattle route from 9,000 nautical miles (nm) through the Panama Canal, to 7,000 nm and the Rotterdam-Yokohama route from 11,200 nm through the Suez Canal, to 6,500 nm. Considering canal fees, fuel cost, and freight rates, Arctic shipping routes offer the potential to cut transportation costs substantially. For instance, the NSR can reduce travel distance by approximately 40%, saving up to 10% in fuel costs when compared to traditional transcontinental routes *via* major canals. However, there are cons to Arctic shipping. A major factor is related to seasonality. The lack of accessibility and reliability contributes to a much higher insurance premium. High icebreaking fees, constraints on sailing speed, and investments in dedicated ships all contribute to high costs and uncertainty, although recent developments suggest that icebreaking ships may not be needed for certain periods.

Infrastructural Limitations

Shipping in the Arctic needs to be supported by reliable, resilient infrastructure (e.g., ports, navigational aids, rescue systems, etc.) and know-how to ensure safety and security and to minimize potentially negative environmental and socioeconomic impacts. Military installations in the Russian Arctic and large port projects (e.g., Yamal) are now under construction. Within Canadian Arctic waters, the only deep-water Arctic port is located in Churchill and is returning to operation in 2018 (following its shutdown in

2016), while a deep water port at the Nanisivik Naval Facility near Arctic Bay on the northern end of Baffin Island is set to open soon, and the community of Iqaluit, on the southern end of Baffin Bay, is set to have a new modern port facility built in the coming years. Still, hitherto, ports and other infrastructures along the Arctic shipping routes are scarce and of low quality. While professional know-how in the construction, maintenance, and operation of such facilities is in serious short supply. All these require capital-intensive investments that, in turn, push up the costs of Arctic shipping. Inevitably, this raises the question as to whether Arctic shipping should be “general” or “specific” to particular type(s) of passengers and/or cargoes. For example, rather than positioning Arctic shipping as an alternative to intercontinental shipping routes based on shorter distance, there are views that shipping in the Canadian Arctic should be oriented toward resource extraction (e.g., oil and gas), food security (e.g., toward the northern communities), and other local activities (e.g., commercial fishing and cruise tourism).

The impacts of Arctic shipping on regional development cannot be ignored, as negative impacts posed by shipping are often generated by vessels. With the highly environmentally sensitive nature of the Arctic area, negative impacts can be substantial even without any serious accidents (e.g., oil spills). Hitherto, the academic and professional communities have not yet reached a consensus on the cost implications regarding insurance, escorts, and emergency response, all of which are far from being straightforward (Ostreng et al., 2013). In addition to environmental concern, there are socioeconomic aspects that need to be considered. In Canada, for example, there are at least 600 indigenous communities scattered across the northern territories and the Prairie provinces (e.g., Manitoba). Any pollution generated by shipping may affect migration routes and marine behaviors that can pose huge impacts on their livelihoods. However, vessel operators may not be aware of such impacts, especially those based in non-Arctic countries that have no direct connections with the Arctic itself. Facing such threats, *A Circumpolar Inuit Declaration on Sovereignty in the Arctic* states the rights of the Inuit (i.e., indigenous people that inhabit the Arctic regions speaking the Inuit language) in terms of natural wealth and resources (Inuit Circumpolar Council, 2015). Thus, Arctic shipping can trigger competing conflicts between global and local interests.

Of the major Arctic routes, the NSR has experienced the greatest increase in marine traffic. This is due to several reasons, including: (1) greater reductions in summer sea ice extent have occurred along the NSR compared to the NWP which is confounded by ice conditions in the Canadian Arctic Archipelago, (2) Russia, the country sovereign over this area, has invested much in terms of icebreakers, infrastructure, and other necessary facilities to make it navigable, thereby building confidence for shipowners and operators to travel along this route, and (3) the routes are better defined compared to those in the NWP (Ostreng et al., 2013). For an area that is estimated to contain much of the world’s hydrocarbon deposits, precious minerals, and other resources, it is a very strategic location for the global economy, wealth, and energy security.

Despite the heated ongoing discussion of sovereignty between Canada and the United States on the Arctic marine channels, the Canadian government has stepped up its work in this area to assure that the development of shipping can take off smoothly. A key benefit of doing such is the benefit that the northern communities are likely to receive. Unlike the Russian side that has a (relatively) high population, it is not the case for the Canadian side. The increased activities along the NWP will, therefore, open the northern communities up and make movement of goods easier. Due to the nature of the Canadian Arctic, communities are mostly accessible by air. This is normally expensive. In this case, although not technically part of the Canadian Arctic area, the town of Churchill (Manitoba, Canada), with its already-established rail links to the south, a port with decent facilities and proximity to the northern regions, has real potential to become an important maritime gateway to the Arctic area. Also, Arctic shipping is likely to bring wealth and opportunities to an otherwise remote community: people could be more willing to move to the communities to work, knowing they are assured of supplies. The cost of living is high in these areas and this discourages people from taking up employment. An improved and fast means of delivering cargo means that employees are assured of food and other essentials. The uncertainty about food and travel could be minimized.

Finally, another aspect of Arctic shipping is cruise tourism. Like many Arctic cities or towns, accessibility in terms of cruise ships could improve the tourist potential of these places. Many would like to know how the Arctic looks and the natural fauna and flora in this area, but the difficulty in traveling through ice has prevented such voyages. Arctic shipping may therefore present an unprecedented opportunity for tourism in the Arctic area.

The Legal Aspects

Regulations and guidelines for Arctic shipping vary from nation to nation. Examples of the regulations used within Canada are provided later.

Regulations Regarding the Arctic Area in General

The Polar Code

The Polar Code (IMO, 2015) stresses that ensuring stricter practice within Polar waters is warranted as an essential and positive development for Arctic shipping. The shipping and resource extraction impact on wildlife (e.g., caribou, seals, etc.) can, in turn, pose key challenges to the indigenous population whose (traditional) livelihoods depend on them. With intensified shipping in the Arctic, the risks to local autonomy and sovereignty may increase as non-Arctic countries, such as China, start to become actively involved. Such potential threats have led to the *Polar Inuit Declaration of Arctic Sovereignty* (2009) that addresses Inuit rights in terms of natural wealth and resources.

United Nations Convention on the Law of the Sea (UNCLOS)

The Law of the Sea, as included in the 1982 UNCLOS, sets out the legal framework for the regulation of shipping based on maritime zones of jurisdiction. The Law of the Sea ensures the power balance of coastal states, flag states, and port states to exercise jurisdiction and control over shipping. However, the jurisdiction status of some Arctic waters, especially internal waters and straits utilized (or potentially to be utilized) for international navigation, remains controversial and could give rise to disputes. Also, Article 234 of UNCLOS identifies coastal state powers to regulate foreign shipping in order to prevent, reduce, and control marine pollution in the Arctic.

Regulations Regarding the Canadian Arctic***The Arctic Ice Regime Shipping System (AIRSS)***

The Arctic Ice Regime Shipping System (AIRSS) is a numerical go/no-go breakdown for vessels facing ice that has been adopted heavily in shipping projections based on climate projections. The AIRSS is developed to manage the risk of pollution in the Arctic due to damage to vessels by ice, highlighting the responsibility of the shipowners for safety and providing a flexible framework for the decision-making process.

Guidelines for the Operation of Passenger Vessels in Canadian Arctic Waters (TP 13670E)

The Canadian Government has drafted the TP 13670E guidelines with the aim of improving passenger ship operations in Canada, including cruise ships. Although not a legally binding document, the guidelines strive to offer a solid framework for Arctic passenger ship operators to operate and manage their ships in a safe and pollution-free way. In addition to operational standards, the guidelines also clarify the division of responsibilities between different agents that have interests in Arctic shipping (e.g., Transport Canada, Canadian Coast Guard, Department of Fisheries and Oceans, etc.). Finally, the guidelines also consolidate the expectations and commitments of those who organize Arctic tourism and trips.

Pollution Prevention Guidelines for the Operation of Cruise Ships Under Canadian Jurisdiction (TP14202E)

The TP14202E guidelines were promulgated by the Canadian Government in 2013. It intends to help cruise ship operators develop better procedures to comply with Canadian legislation on Arctic shipping and pollution. Simultaneously, the guidelines suggest best practices that cruise ship operators are strongly encouraged to follow. The guidelines state clearly how cruise ship operators should undertake waste management (e.g., X-ray development fluid waste, contaminated materials, garbage, oily water residues, etc.). Finally, the guidelines also offer a framework on reporting, inspections, and the preparation of training and educational materials.

Other Legislation

In addition to the aforementioned, there are several legally binding laws in Canada that address Arctic shipping in general. These include the Arctic Waters Pollution Prevention Act, Canada Shipping Act 2001, Marine Liability Act, Marine Transportation Security Act, Coasting Trade Act, and the Canada Labor Code. Although these acts and legislation are not directly related to Arctic shipping, each of them plays an important role in ensuring safety, the quality of health, property, and the maritime environment within the Arctic region.

Key Features of Air Cargo

We begin with the vocabulary. In the past “cargo” often referred to goods conveyed by ship, boat, or aircraft, whereas “freight” referred to goods conveyed through trucks and trains. With the subsequent recognition that virtually all supply chains are multimodal, this distinction has largely disappeared. Here, the terms cargo and freight are, therefore, used interchangeably. The term air-courier (or air package) services is often encountered and relates to the rapidly growing activity of moving small consignments by air, often as part of a door-to-door intermodal service. Economic development is treated generally to include increases in income or employment but is also seen to include the modernization of industrial structure in a region.

Now, let’s see some basic statistics. In 2017, according to the UN’s International Civil Aviation Organization, air transportation was globally responsible for 231,215 million ton-kilometers of cargo, including mail. Of this, 199,835 million was international. Air cargo revenue in 2018 was estimated at \$109.8 billion. Much of the cargo traffic moves through the world’s largest cargo airports. In 2018, the five largest were Hong Kong (5,120,811 tons), Memphis International Airport (4,470,196), Shanghai Pudong International Airport (3,768,573), Incheon International Airport (2,952,123), and Ted Stevens Anchorage International Airport (2,806,743). In terms of airlines, in 2017 Federal Express, which mainly offers air-courier services, was the largest carrier providing 16,851 million freight ton-kilometers, followed by Emirates (12,715), United Parcel Service (11,940), Qatar Airways (10,999), and Cathay Pacific Airways (10,722).

Air cargo services can alleviate surface infrastructure deficiencies by providing fast and reliable transportation for high-value and perishable products. It can also offer alternative distribution systems by providing a different purchasing mechanism, including e-commerce with next-day delivery instead of going to the physical store. Additionally, it provides suitable transportation for perishable luxury and exotic agricultural goods for affluent consumers, such as flying flowers and produce from Ecuador and Colombia to the United States and from Kenya to Europe. Further access by air cargo suppliers may permit firms to quickly take advantage of new market opportunities. This is because changes in freight links require minimal infrastructure investment. Inbound air cargo enables businesses to improve their physical capital stock by providing a reliable transportation mode for moving high-value equipment, machinery, and spare parts.

Access to air cargo can affect firms’ strategies. For example, being fast and reliable, air cargo can be used for emergency delivery of products allowing reduced inventory holding and just-in-time business practices. This permits disintegration of production of components and semi-processed parts as elements of an integrated supply chain. Availability of air cargo can allow firms to gain competitive advantage by using low-cost local labor and rapid access to main markets for manufactured goods, such as clothes and some electronics manufactured in, say, China and Korea for US consumers with shelf life that rapidly decay with fashion dictates.

Air transportation, therefore, has important attributes that can help facilitate economic development (Kasarda, 1991). By linking together geographically separated, but complementary, economic activities, it can generate various forms of economies of scale and allow those of specialization to be realized. Basically, it can generate economies of agglomeration (Venables, 2006). But whether this will occur, its extent and which areas will benefit is an empirical matter. It is also a matter of timing. For example, in terms of freight, while the economic growth of the likes of China, India, and Brazil has led to an overall increase in demand for the movement of heavy, bulky commodities that mainly make use of maritime modes, the rapid expansion of high-technology industries and the demand for more “exotic” products stimulated by higher incomes has seen consistent growth in air cargo.

History

The changed institutional environment from the late 1970s fostered growth in air transportation by removing the stringent regulations that had tended to stymie both air cargo and passenger aviation following the 1944 Chicago Conference. While this added some flexibility to the pre-1939 situation, rather than pursuing more liberal, and possibly multilateral policies, the tendency of countries to seek protection of their own carriers within bilateral air service agreements hampered the growth of the industry. Domestically, the geographically large nations suited to air cargo activities acted to control market entry and air cargo rates.

The first two decades of the 21st century has also seen the evolution of Internet technology and this has led to the explosive growth of e-commerce. Easier access to the global marketplace, accompanied by a rise of e-commerce, has radically changed business and consumer buying behavior. The shortening of product life spans in many industries (e.g., computers, pharmaceuticals, and designer clothes) has meant manufacturers and retailers putting a premium on reducing inventories. As a result, in 2018, e-commerce sales at \$2.8 trillion were more than double the \$1.1 trillion spent in 2012. Much of this has involved air movements, including direct from producer to consumer logistics. This had clear impacts on sectors such as retailing, with resultant shifts in location patterns and supply chains, with some companies adopting “virtual warehousing,” involving keeping goods in transit rather than using storage. Others, notably e-commerce retailers, rely on strategically located “fulfillment centers” that enable speedy and economical delivery of goods bought online.

The result overall is that, in quantitative terms, 2018 saw the annual cargo carried by air transportation to be only 1% of total world trade by tonnage, but over \$6 trillion, or 35%, in terms of value. Revenue-ton kilometers of air cargo grew annually by 2.6% between 2007 and 2017 despite the global economic recession. Boeing’s *World Air Cargo Forecast 2018–2037* (Boeing Commercial Aeroplanes, 2018) predicts this annual average rate will average 4.2% between 2018 and 2037. There is, however, quite a substantial range around this average, with growth within China’s domestic market growing by an average of 6.2% but intra-European by only 2.3% and Middle East–Europe by only 3.2%.

The traffic, however, is not evenly spread and nor is the way it is carried. Dedicated air freighter routes are, for example, concentrated on a few trade lanes, notably East Asia–North America and East Asia–Europe. In contrast, passenger networks are much broader and include destinations where cargo demand is minimal. These factors explain the load factor differential between belly space services and freighters, which average about 30% and about 70%, respectively, and the fact that freighters generate more than 90% of the air cargo industry’s revenue.

There has also been an increasing internationalization of the air cargo industry brought about through the outward expansion of former domestic carriers, the merging of two or more formerly domestic carriers, and the creation of alliances of airlines. This has been mirrored in the provision of air cargo-related services. Much of this has involved developing countries and new markets, most notably in Asia.

The range constraints on fully loaded passenger aircraft and their limited services to major cargo airports also contribute to the differences. Express carriers such as UPS and FedEx operate substantial freighter fleets, flying more than half of the wide-body freighters and generating 43% of air cargo revenues in 2017. Low-cost carriers have increased their share of air cargo traffic, particularly in Southeast Asia, but are still estimated to carry less than 2% of cargo traffic.

In terms of the implications of these trends on economic development, at the global and the mega-region level there is a clear correlation between economic development and air cargo provision; for example, annual revenue-ton kilometers fell between Europe and slowly developing Africa by 1.0% from 2007 to 2017, but rose by 4.2% between Europe and dynamic South Asia.

The Air Cargo Supply Chain

Cargo aviation is always one part of a longer supply chain involving production, storage, information systems, and a variety of feeder and distribution modes, as well as airlines. Because of this, and the numerous other factors, it is difficult to isolate the specific development effects associated with it. What is of more relevance, and more easily assessed, are the roles the air cargo supply chain can play in stimulating economic development.

Many of the earliest aviation services were for mail transportation. The first reliable scheduled airmail service began in May 1918 when a daily, round-trip service between New York and Washington, DC, was started, with a stop at Philadelphia. Airmail continued to be the main form of air cargo business during the interwar period. It was seen by the imperial powers as a means of tying empires together, by large countries, as a way to integrate and develop more remote areas, and by aspiring military powers to gain influence in lesser developed economies. As technology improved so did the range and capacity of the networks. Germany, for example, had services to South America from 1934 that, amongst other things, involved a catapult launched flying boat refueling at a permanently stationed tanker in the South Atlantic and dirigibles. By World War II planes such as the German Junkers Ju 52, which could carry up to 3 tons of cargo, were used for supplying mining and remote areas in many parts of the world.

From the late 1940s, when large numbers of former military aircraft became available for civil use, air cargo traffic grew considerably. Beside mail and package services, which were often shipped on passenger planes, converted large bombers began to be used as dedicated freighters. The advent of improved technology, most notably wide-bodied freighters and passenger aircraft with significant belly-hold capacity, together with increased efficiencies that have been built into the materials handling and air cargo systems, has significantly reduced the costs of air cargo.

Figure 1 The air cargo logistics supply chain.

On the demand side, as industry has increased its production of high-value, light-weighted goods, such as microelectronics and pharmaceuticals, 80%–90% of their international movements are by air. The shortening of product life cycles and adoption of just-in-time manufacturing necessitates fast and reliable transportation to minimize inventories, warehousing, and packaging. As a consequence of these developments, the modern air cargo industry serves a multiplicity of functions.

Fig. 1 provides a stereotyped abstraction of the sorts of activities involved in providing air cargo logistics. It is not a simple matter of aircraft. Indeed, the strict air transportation part of the chain, highlighted in bold, is relatively limited but it does entail a significant variety of actors serving various supporting functions higher up the chain. These may be coordinated through the interactions of markets or by a coordinating agency, such as an integrated carrier, providing institutional integration and planning of the supply chain. Which is optimal is dependent on the cargo to be moved, the nature of the businesses involved, and the larger institutional environment in which the chain is set. The nature of the chain in turn affects the scale of any economic development effect and its location.

Focusing particularly on the trunk-haul air cargo part of the chain that has the most obvious development implications, this can pose serious supply issues. In particular, air cargo does not have the bilateral demands of return traffic as with passenger services. Individuals largely make return flights, but air cargo carriers have to find backhauls or fly half the time largely empty. In many cases involving developing countries, the bulk of traffic consists of exports, often natural, final products, and, in others imports, often of components and replacement parts. Use of belly-hold capacity in areas between regions with large, relatively high incomes can help spread the costs of a paucity of backhaul traffic. Complex route patterns can also help, but this may lengthen haul time and reduce service frequency. Thus, while aviation may have the potential in many cases to foster economic development, there can be threshold factors that can stymie this.

Nature of the Economic Development Impacts

The economic development effects of the supply chain can occur at different points in the chain. But even before this, air cargo can result in significant economic development as the consequence of the locations where the aircraft are constructed. The main

suppliers of both dedicated cargo carriers and the passenger aircraft that provide belly-hold capacity, Boeing and Airbus, have had major economic development impacts at their main production locations, Seattle (about 80,000 direct employees) and Toulouse (about 32,500 direct employees), respectively, and locations supplying components and undertaking aircraft maintenance and conversions. It is impossible, given the dual nature of most large aircraft and the numerous conversions from passenger to cargo planes, to isolate the number of jobs that can be attributed to cargo-plane manufacture. But most of these jobs are relatively highly paid, creating significant income in the area involved with subsequent multiplier effects.

It is around the nodes in the supply-chain, the airports and airfields, that economic effects are largely seen. There are the activities at the airport itself involving the handling and transshipment of cargo, its storage and sorting, its security, and associated data processing. The maintenance and handling of aircraft, and of the associated airport facilities, adds further jobs. These all, to varying degrees, through the incomes paid labor and fees paid companies, generate additional local fiscal multiplier effects in the local economy. The availability of air cargo services can further attract businesses that make use of air cargo to the hub's location allowing them to reduce surface transportation costs and also speed up their own logistics. This results in the creation of new industries and activities in the area; these are often called induced multiplier effects (Raguraman, 1997).

Empirical Findings

While the largest economic benefit of increased air cargo connectivity lies in its impact on the long-term performance of the wider economy through enhancement of the overall level of productivity, isolating the effects of any particular cargo mode, including air cargo, despite a mass of empirical studies, has not been easy. First, few movements are by a single mode. For example, Memphis, Tennessee, the main logistics center for FedEx Express—the world's largest airline in terms of freight tons flown and ninth largest in terms of fleet size—sees well over 1.5 million packages pass through it each night. But this is part of a larger FedEx structure that, in addition to its major cargo airport, also makes use of five Class 1 railroads and the I-40 and I-50 interstate highways that link the city to the national road network. The air cargo contribution to the city's economy is unquestionably large, but what would it be without the other transportation services?

Secondly, passenger and freight aviation are very often jointly supplied. At one level they generally share the same infrastructure, airports, and air traffic control, and at another considerable freight is moved in the belly-hold of planes that carry passengers as well. There are also complements in demand. Many tourist destinations, and notably island destinations, for example, not only rely on air transportation to bring their customers but also to bring in materials such as food, retail goods, and components necessary for a successful hospitality trade. Even with more traditional engineering industries where spare parts and components may be moved by air, these may be in the holds of planes carrying marketing, finance, and other personnel.

Causality is another matter often poorly dealt with in empirical analysis. Freight aviation may bring jobs and income to an area, but equally high-income, high employment areas can be catalysts for air services (Hakim and Merkert, 2016). Indeed, global air cargo transportation correlates 98% with world GDP growth, but does it cause it or result from it? There are statistical techniques that, with suitable data, can in some cases isolate the directions of causality, but these have not been widely used in studying the air transportation/economic development interface.

Fourthly, investment in air cargo facilities has an opportunity cost. Inevitably, while it might increase jobs and incomes where it is located, this may entail transfers of business from other areas with consequential reductions in jobs there. From an economic perspective, if there is a net gain in economic activity this may be seen as national development. But it can raise questions when it entails transfers of economic activity from a poorer to a wealthier region. The latter is not uncommon given the nature of the aviation sector and the types of things that its cargo industry moves.

But even allowing for all these caveats, there are clear cases where air cargo has been found as a necessary input for economic development. This work can be divided into that focusing on its areal implications, say the development of cities, or of its effects on specific industrial sectors, such as perishables.

National Development

Separating out the role of air cargo in global or even national economic development is impossible; there are just too many things that affect macro-level developments. At best it can be said that the emergence of freer trade in 1995 under the auspices of the World Trade Organization increased demands for international cargo services. The impacts of the resultant increase in the supply of air cargo services on national economies are difficult to isolate given other significant economic and political trends since then. What does seem important is the stage in an economy's development. Advanced air cargo services in particular have proved important in core economies and world cities in postindustrial economies, where the preponderance of knowledge-based functions is located. But at the other extreme, it has been important to less developed countries in developing labor-intensive, export-oriented industries, such as floriculture, in which they have a comparative advantage.

One thing that is clear is that air-based courier delivery services such as FedEx, UPS, DNL, etc., have been facilitators of e-commerce on a global scale and with this has come changes in the ways that business in general is conducted. Air-courier delivery services have, for example, changed how the retail sector functions, how sectors like apparel are sourced and function, and reduced inventory requirements in virtually all sectors. Whether this is development or a change in doing things is debated, but the effect has been substantial. We have earlier noted the large-scale, international network services of these courier service suppliers.

Regional Development

At the meso-regional level, the limited econometric analysis that has been conducted offers somewhat conflicting results. [Button and Yuan \(2013\)](#), for example, examined trends in employment and income for US metropolitan statistical areas with a focus on causality rather than simple correlation. Granger Causality testing based on panel data covering 35 airport and 32 metropolitan areas from 1990 to 2009 indicated that airfreight was a positive driver for local economic development at this level of spatial aggregation.

Another US study by [Green \(2007\)](#) looked at the impact of airports on the population and employment growth of 83 US metropolitan areas. After both controlling for a variety of other factors and considering causality, he found that while passenger airport activity is a powerful predictor of growth, cargo activity is not. The reason seems to be that the major cargo hubs, such as Memphis, tend to be highly automated and thus have limited direct employment effects and small local multiplier effects on their economies.

Sectoral Developments

Turning to some industries that make considerable use of air services, in 2008, about 15% of global air cargo traffic was made up of perishables and exotics where suitable transportation is defined in terms of speed, reliability, and security. In terms of trends, however, changes in maritime technology mean that computers and other goods that previously had been moved by air are increasingly being transported by ship. On the other hand, perishables, such as fruit and flowers, have experienced an annual growth in volume of over 7%, or put another way, as a share of new freight ton-kilometers they have been growing at about 12%. Much of this has been because of developments in some established production areas, but new areas are also being developed.

One example of the role of air cargo stimulating this type of economic development can be seen in its facilitating growth of the flower industry in the Victoria Lake region of East Africa, mainly Kenya, and around Addis Ababa, Ethiopia ([Button, 2020](#)). These two regions together account for about 20% of the world's cut flower exports. Without good surface access to Nairobi's and Addis's international airports, suitable refrigeration at the airports, and adequate, reliable airlines to take the blooms to European and Middle-eastern markets, the industry could not have grown. But the spread of the economic development impacts is quite small. For example, 70% of Kenya's flowers are grown at the rim of Lake Naivasha, northwest of Nairobi, and Ethiopian's floriculture industry involves a growing area of 1442 hectares. Both, however, do employ significant numbers of unskilled workers, and, notable from the economic development perspective, the vast majority are women.

But there has also been economic development in parts of South America, notably regions within Argentina, Peru, and Ecuador, that have depended on air cargo to move perishables, notably flowers, to the US market, and less so to Europe. Vega, for example, found that between 2000 and 2006 the value of perishables and exotics flown from South America to the United States grew by almost 50%, and specifically perishables from Peru by 20.1%, Argentina by 18.8%, and Ecuador by 11.3%. In terms of the economic development standpoint this, by providing jobs, improved the socioeconomic condition of impoverished rural communities. The Ecuador flower industry, for example, added an average of more than 5500 jobs a year, mainly in areas where floriculture is the single largest employer ([Vega, 2008](#)).

In terms of industrial components, [Bowen and Leinbach \(2003\)](#), looking at electronic manufacturers in Singapore, Malaysia, and the Philippines found that knowledge-intensive air cargo services played a significant role in the development of the industry. Findings of a similar general nature were found by [Aunurrofik \(2018\)](#) in a study looking across Indonesian regions. In 2011, the Chinese city Zhengzhou opened a 5 km², customs-free bonded zone on and adjacent to the airport for high-value, time-critical manufacturing and distribution. Foxconn located a manufacturing campus there that employs 240,000 workers assembling Apple's iPhones and other digital devices. Smartphone output from this doubled the value of the province's exports in 2012.

Introduction

The air freight logistics industry has become an increasingly important part of the modern world economy. In 2018, airlines transported just over 63 million metric tons of goods valued at USD 6.5 trillion, including products as diverse as cut flowers, cool chain pharmaceutical products, consumer electronics, perishable foodstuffs, and medical diagnostic devices (IATA, 2019). In many respects, the shipment of high value-to-weight commodities by air has become a crucial link in global trade, where a premium is increasingly placed on speed and timely deliveries. Although air freight shipments may account for less than 1% of global trade by volume, they now make up 35% of all global shipments by value (Shepherd et al., 2016).

The aim of this article is to better understand the changing role of air freight logistics in the contemporary global economy. This is achieved by first outlining the historical evolution of global air freight services and the geography of the major cargo airports. We then discuss Kasarda and Lindsay's (2011) theory of airport logistics-centered growth nodes, focusing on the aerotropolis concept. This is followed by a section that highlights the complex and heterogeneous nature of the air freight logistics market and concludes with an analysis of the major trends and future challenges facing the industry.

Growth and Change in Air Freight Demand

Although the 1919 Paris Convention and the 1925 Warsaw Convention essentially established the international regulatory framework that would facilitate the growth of air cargo, most developed nations initially utilized air space to primarily develop extensive air mail networks, both domestically and internationally (Budd and Ison, 2015). By the 1950s, demand for air freight services was growing, partly because longer-range, higher-capacity, and more fuel-efficient jet aircraft, such as the Boeing 707 and the Douglas DC-8 among others, had been introduced to the market, some of which are still in use today as re-engined freighters. These planes helped reduce flight costs, while new airline business models simultaneously emerged to maximize the revenue that could be obtained from transporting air freight.

Since the 1970s, demand for air freight has remained strong, with the only significant reductions occurring partly as a consequence of the first Gulf War in the early 1990s and the September 11th World Trade Center attack in 2001. Fig. 1 illustrates air freight traffic trends from 2004 through 2019, where the only substantive drop-off in demand was in response to the 2008/9 global economic recession. Although air freight traffic was relatively sluggish from 2010 until the early part of 2016, in response to the stagnant economy, traffic rebounded in 2017 with near-record growth driven by the global inventory restocking cycle and buoyant demand for high-value manufactured exports (Air Cargo World, 2018). More recently, the spread of nationalism, populism, protectionism, and trade tensions, particularly between the United States and China, have all acted to stymie growth rates in both 2018 and 2019. Others have also observed that additional factors, such as the increased competition in the air freight industry, fuel price volatility, modal shifts to cheaper sea shipping and overcapacity in the air freight sector, have all conspired to depress air cargo yields (Air Cargo World, 2019; Budd and Ison, 2015, 2017; Kupfer et al., 2017; Merkert et al., 2017).

Despite these recent trends, air freight has experienced a relatively steady long-term growth rate over the past fifty years, and in its recent World Air Cargo forecast, Boeing projected that from 2019 to 2038 air cargo operators will need more than 2800 additional freighters (Boeing, 2019). Although freighters (or all-cargo aircraft) comprise just 8% of the total commercial jet fleet, they carry more than 50% of all air cargo traffic. Boeing also expected global freight traffic to double with 4.2% growth annually largely due to the ongoing rise of e-commerce, with key markets including East Asia–North America, East Asia–Europe, and intra–East Asia.

Figure 1 Worldwide air freight traffic: 2004–2019 (Million Metric Tons). Source: Data from IATA (2019)

The World's Largest Cargo Airports and the Aerotropolis Phenomenon

In 2018, the 20 largest cargo airports handled 51 million metric tons of cargo, accounting for 42% of global air cargo volume (ACI, 2019)—see Table 1. The major air cargo airports of the world play a vital role in air freight logistics, acting as the key interface between land and sky, although the spatial distribution of air freight demand is highly uneven by airport, with a small number of air freight nodes dominating the global network (Fig. 2). In 2018, the five largest cargo airports by weight included Hong Kong (5.1 million tons), Memphis (4.5 million tons), Shanghai (3.8 million tons), Incheon (2.9 million tons), and Anchorage (2.8 million tons).

Although air freight services operate on all seven continents, the majority of flights are focused on North America, Western Europe, the Middle East and East Asia. Most of the world's major cargo airports are located in heavily populated metropolitan areas and/or substantive manufacturing centers. Some exceptions to this rule include Anchorage (ranked fifth in the world), which functions largely as an important transit and refueling layover given its strategic location at the intersection of major world trade routes. Other major exceptions include the Federal Express and UPS hubs located in Memphis (ranked second) and Louisville (ranked seventh), respectively. Neither of these airports have major passenger facilities and both metropolitan areas are only medium-sized, each with less than 1.5 million in total population.

In recent years, the relative ranking of the major cargo airports has changed quite dramatically with a noticeable decline in the relative importance of Western European and North American hubs (e.g., London and Miami) and a fairly dramatic rise in the significance of both East Asian and Middle Eastern airport operations (e.g., Taipei and Doha). In 2000, 14 of the top 20 cargo airports in the world (by weight) were located in either the United States or Western Europe. By 2018, the relative mix had changed substantially, with 10 of the top 20 cargo airports now located within either East Asia or the Middle East, due to rapidly emerging markets in places like Shanghai, Dubai, Taipei, and Doha (Fig. 2).

Many observers have argued that this process of intense geographic concentration and regional specialization has fundamentally reshaped the air freight industry and related global value chains (Alkaabi and Debbage, 2011; Boonekamp and Burghouwt, 2017; Budd and Ison, 2015; Gardiner et al., 2005; Walcott and Fan, 2017). One of the most provocative conceptual frameworks for much of this research

Table 1 Top 20 air cargo airports, 2018

<i>Airport</i>	<i>Total cargo metric tons (000's)</i>
Hong Kong (HKG)	5,120
Memphis, US (MEM)	4,470
Shanghai, China (PVG)	3,768
Incheon, SK (ICN)	2,952
Anchorage, US (ANC)	2,806

agenda is provided by [Kasarda and Lindsay \(2011\)](#). They argued that the rapid expansion of business-to-business (B2B) supply-chain transactions and the elevated emphasis on timely, fast, and reliable deliveries have played a fundamental role in generating new planned airport-related agglomerations in places like Amsterdam, Seoul, and Dubai that are fundamentally linked to the air freight logistics sector. The concept of the airport city, or what [Kasarda \(2013\)](#) has coined the “aerotropolis”, is based on the notion that some freight airports are now shaping business locations and urban development patterns, like highways, railroads, and seaports have in the past.

Critics have suggested that the aerotropolis concept is heavily contingent on relatively affordable oil prices and overlooks the substantial carbon footprint of many air freight logistics operations ([Charles et al., 2007](#)). Others have questioned the loss of natural lands, population displacement issues, problems linked to excessive aircraft noise and general lack of urban ambience associated with the aerotropolis model of development ([Bridger, 2015](#)). Despite these critiques, the aerotropolis concept is in some ways the explicit spatial manifestation of the agglomeration of air freight industries, given that it is functionally linked to time-sensitive manufacturing, e-commerce, telecommunications and third-party logistics firms. However, the air freight industry is both complex and highly heterogeneous ([Chu, 2014](#); [Kupfer et al., 2017](#); [Merkert et al., 2017](#))—a sector of the economy that defies simplistic classifications and sweeping generalizations.

The Complex and Heterogeneous Air Freight Logistics Market

Although air freight logistics plays a crucial role in the air transport chain and in the larger globalized economy, it is a highly heterogeneous industry with a wide variety of major actors and traffic flows. Airports and airlines obviously lie at the heart of most air freight logistics operations, but they are surrounded by a complex web of players including handling companies, customs brokers, and maintenance and fuel suppliers that can make any conceptualization of air freight logistics appear contrived ([Merkert et al., 2017](#)).

That said, the air freight supply chain consists of three major actors: shippers, forwarders, and carriers ([Boonekamp and Burghouwt, 2017](#); [Popescu et al., 2011](#)). The shipper can be thought of as the party that wants to have a good shipped from one place to another. The forwarder arranges the door-to-door transport of the shipment and handles all of the necessary documentation. Finally, the carrier is responsible for the airport-to-airport shipment.

With respect to the various carriers, [Kupfer et al. \(2017\)](#) have recently proposed an alternative business model for air cargo delivery and suggested that an important distinction should always be drawn between integrated and nonintegrated air cargo carriers in any discussion of air freight operations ([Fig. 3](#)). They pointed out that most of the companies in the air freight industry operate as nonintegrated service providers and they include forwarders, combination carriers (e.g., IAG, Lufthansa, Emirates) and all-cargo carriers (e.g., Kalitta Air, Southern Air, Cargolux). Combination carriers transport passengers along with cargo in the belly-hold while all-cargo carriers usually operate contract services or provide guaranteed space for third party operators and are not involved in the passenger business. However, the distinction drawn between combination carriers and all-cargo carriers is not always clear because many of the world's major passenger carriers also operate dedicated cargo-only aircraft alongside their passenger fleets (e.g., Lufthansa Cargo and Emirates Sky Cargo)

Figure 2 Spatial distribution of the top 20 largest cargo hubs in the World, 2018 (top) and 2000 (bottom). Source: Data from *ACI (2019)*

By contrast, integrated or express carriers (e.g., FedEx, UPS, and DHL) provide door-to-door collection and delivery services using a fleet of aircraft and road vehicles. In this sense, the integrators tend to own all the assets of production throughout the entire logistics value chain and, consequently, play a formidable role in shaping the air freight industry. Based on total scheduled freight ton-kilometers (FTKs) in 2017, the largest (FedEx), third largest (UPS), and fifth largest (DHL) cargo airlines worldwide were all integrated carriers (*Table 2*).

However, *Merkert et al. (2017)* remind us that any business model should also consider the vast network of service providers that act as critical external influences on the air freight logistics supply chain (*Fig. 3*). These factors can include the broader regulatory environment and labor pool as well as the practices and policies of the airport authority, among other things.

Although air freight can be transported in slightly different ways (e.g., integrated vs. nonintegrated carriers), the vast majority of approaches essentially offer the same basic service. However, *Budd and Ison (2017, p.36)* have pointed out that the decision to fly freight on a dedicated freighter (i.e., all-cargo carrier) as opposed to belly-freight on a combination carrier or via an express carrier “is

Figure 3 Business model of air freight delivery. Source: Modified from Kupfer et al. (2017) and Merkert et al. (2017)

Table 2 Top 10 cargo carriers, 2017

Airline (or airline group)	Total Cargo Traffic (FTK millions)
Federal Express	16,911

a commercial decision based on considerations of cost, convenience, reliability, the commercial value of the shipment and required levels of service, as well as variables including an airline's market share and market power." The end result is that air freight logistics is an industry that can often exhibit very different cost structures, operating characteristics and spatial patterns of supply and demand.

One major commercial challenge facing all air freight operators is the unique geography of many air transport routes (e.g., East Asia–Western Europe). Unlike the bi-directional nature of much air passenger transport, in air freight logistics an outbound flight is not necessarily complemented with a return or backhaul flight. The uneven spatial nature of demand is a consequence of moving goods from their site of manufacture (frequently East Asia) to their point of consumption (e.g., Western Europe and North America). To mitigate the so-called "backhaul problem", many carriers are forced to operate triangular, often times intercontinental, routes to avoid flying empty or with minimal freight loads. Although this may help to promote higher loads, it can also increase shipment times and, consequently, may not be suitable for certain types of perishable or time-critical commodities (Budd and Ison, 2017).

Although the dynamics of the air freight carrier industry are relatively well known, much less research has been conducted on the major air freight forwarders (Fig. 3). Freight forwarders act as the intermediary between shippers and carriers, as they typically

Table 3 Top 10 freight forwarders, 2018

<i>Provider</i>	<i>Country</i>	<i>Airfreight metric tons (000's)</i>
DHL Supply Chain and Global Forwarding	Germany	2,150
Kuehne and Nagel	Switzerland	1,743
DB Schenker	Germany	1,304

Bolloré Logistics	France	690
DSV ^a	Denmark	689

^aDSV acquired Panalpina in early 2019 making the combined company the third largest air freight forwarder in the world.

Source: Data from *Air Cargo World* (2019)

consolidate the merchandise of individual shippers into larger quantities of freight and then book cargo space with the major air freight carriers to ensure a more efficient and economical shipment (Chu, 2014). Based on airfreight tons shipped in 2018, the leading freight forwarders included German-based DHL Supply Chain and Global Forwarding (2.15 million tons), Kuehne and Nagel (1.7 million tons), and DB Schenker (1.3 million tons) (Table 3). Unlike the world's largest cargo airports, the leading freight forwarders are still largely based in Western Europe or the United States, although companies like China's Apex Logistics International and Hong Kong's Kerry Logistics are both rapidly moving up the rankings.

Major Trends and Future Challenges

Given the markedly heterogeneous nature of air freight logistics, it can be difficult to predict major trends and future challenges. Merkert et al. (2017, p.3) have argued that "there is no such thing as a single, unique, air freight model." However, it appears that at least two major drivers of growth will shape the broader market in the immediate future and these include the ongoing global increase in e-commerce and the cost of jet fuel.

The rapid rise of e-commerce has connected retailers and consumers in different geographic locations across both domestic and international markets, subsequently driving up the demand for faster, more reliable air freight delivery services. The growth in e-freight transactions, as well as information and communication technologies, are likely to lead to additional innovations and efficiencies in the air freight logistics supply chain. Some of these innovations have the potential to be disruptive, including the growth of artificial intelligence programs that can analyze supply chain "big data" and use machine learning to identify the hidden patterns of daily e-commerce. It may also include the implementation of block chain-based global trade digitalization platforms that grant trusted parties exclusive access to data in real-time, although the full potential of this technology for air freight logistics is still open to question.

Jet fuel prices will also substantially impact the demand for air freight transport. If oil prices (and by extension air freight rates) increase, then the demand for air freight logistics may fall or the services will become more expensive. Budd and Ison (2017, p.39) have pointed out how the period of high fuel prices in 2008/9 "had the effect of temporarily leading to a rise in slow shipping and a shift to slower but cheaper land and sea transport." Another round of modal substitution would likely occur if fuel prices rise in the near future.

The heavy reliance on fossil fuels and the related carbon emissions (Debbage and Debbage, 2019) also have the potential to radically reconfigure air freight supply chains. Recent research has suggested that air freight transportation can produce up to 40 times more carbon emissions than maritime transportation (Howitt et al., 2011). Consequently, the ongoing efforts to "decarbonize" the economy, such as placing CO₂ labels on airfreighted produce, may have the potential to substantially alter shipper and consumer behavior, particularly as the so-called "flight shaming" eco-movement gains momentum.

Despite these caveats, similar trends are expected in the near future regarding the continued expansion of air cargo services and infrastructure in East Asia and the Middle East. An elevated demand for express services for certain specialist products, particularly cool-chain pharmaceuticals, cut flowers, electronics and medical diagnostic devices, is also anticipated. Additionally, although air freight logistics has not followed the trend observed in the passenger market, where most carriers have joined one of three large strategic alliances (i.e., Star, OneWorld, or SkyTeam), expect the progression towards consolidation in the air shipment industry to continue unabated. Achieving economies of scale and scope at both airports, and through the value chain, allows shippers and freight forwarders to achieve efficiencies of volume as either belly freight or through full-freighter aircraft (Merkert et al., 2017).

Conclusions

In general, air freight logistics has experienced steady growth over the last 50 years. However, it is a complex form of transportation due to the heterogeneous nature of the industry, which has also contributed to a fairly uncertain future trajectory. Despite various

challenges facing the industry, air freight logistics will likely remain a crucial part of the global supply chain over the long-term, particularly regarding the rapid shipment of high-value, low-weight products. Overall, air freight is a key element of the globalized economy and much more than simply a “by-product” of passenger transport.

Despite its importance, however, this form of transportation remains under-examined from both theoretical and empirical research perspectives. Budd and Ison (2015) make a persuasive case for why there has been a general lack of scholarship focused on air freight logistics. They argue that the relative “invisibility” of air freight in much academic research is largely explained by the sector’s unique and distinctive operating characteristics. “To serve the demanding time-sensitive requirements of global logistics, just-in-time manufacturing and international commerce, air cargo operations typically occur during the hours of darkness, at anti-social hours and at secure inaccessible facilities, bonded warehouses and multimodal logistics centers that are often located at a distance from passenger terminals” (Budd and Ison, 2015, p. 164). The implication is that air freight logistics has tended to operate “in the shadows” with respect to academic research in favor of the more visible, “interesting” and culturally familiar network of air passenger airlines. The goal of this article was to shine more light on this crucially important form of transportation with the hope that the research imbalance regarding air freight logistics will be remedied in the near future.

Future research questions should focus on elevating our understanding of the key decision-making processes that determine the choice of an air freight carrier and airport relative to alternative shipping modes (by road, rail or sea). Additionally, what are the key drivers that shape the air freight logistics supply chain dynamic? How does the relatively high spatial concentration of the supply of air freight services to specific airports and particular carriers contour the geography of demand? In what way will the expanding regulations linked to carbon emissions impact supply and demand in air freight logistics? How will the recent development of the Amazon Air cargo fleet and the experimentation with drone delivery through Amazon Prime Air impact this form of transportation? Although not a complete or comprehensive list, these questions highlight the range and diversity of potential research questions that still remain to be fully answered. It is clear that much more research is needed if we are to more completely understand the dynamics that drive air freight logistics – a crucially important part of the contemporary global transport system.

Introduction

The role of marketing in air transport has evolved to extend beyond mere travel promotion to incorporate the entire product, planning, and purchasing process. Airline services are perishable, heterogeneous, and intangible commodities, and many specialists and technologies are involved in their creation. Traditionally the four Ps—of product, place, promotion, and price—have been used in the study of airline passenger services marketing (Waguespack, 2018) but the characteristics of air freight marketing remain relatively underexplored. The purpose of this entry is to identify the principal ways in which air freight services are marketed and discuss possible future trends. The chapter begins by introducing and defining the scope and characteristics of the global airfreight sector before moving on to consider the ways in which both airline and airport airfreight services are marketed.

Air Freight Defined

Between the first dedicated air freight flight, which took off in the United States in November 1910, and today, the conveyance of time sensitive, high value, and perishable commodities by air has developed into a multitrillion dollar sector of the commercial air transport industry. In 2017, 62 million tons of freight with a combined value of US\$6 trillion (representing 35% of international trade by value) was transported around the world by air (ATAG, 2018). The ability to routinely transport large volumes of high value-to-weight and often time critical consumer goods, industrial components, express consignments, medical samples, pharmaceutical products, perishable commodities, and livestock around the world by air has become essential to the functioning of the modern world economy. Yet the sector is volatile, cyclical, and vulnerable to a range of external influences, which suppress demand. These include the state of the global economy, changes to international trade tariffs, the introduction of new technologies, new security interventions, and alterations in patterns of consumer demand. Almost from its inception, marketing has played a crucial role in stimulating and sustaining demand for air freight services. However, the particular form and function of air freight provision means that both the message and the media that are used to market freight services exhibit distinctive characteristics, some of which differ significantly from conventional air passenger services marketing.

Air freight describes the transport of goods and commodities (other than mail and passengers' luggage) by air. It is distinct from "air cargo," which comprises both the carriage of freight (excluding passengers' luggage) and mail (which includes letters, documents and parcels carried under the terms of a national postal convention or postal regulation). Depending on the nature of the consignment and the speed with which it needs to be delivered, air freight can be classified as being express (urgent), general (less urgent or routine), outsize (usually heavy and/or bulky loads that cannot fit in the holds of conventional passenger aircraft), specialist (such as temperature sensitive pharmaceutical products and live animals), or humanitarian freight (such as tents, food and water purification equipment that is required in the aftermath of an emergency).

Unlike passengers, who can only travel in dedicated aircraft specifically designed for the purpose of human conveyance, air freight can be transported in the holds of regular (often scheduled) passenger flights as "bellyhold" freight or as "pure freight" in dedicated freight-only aircraft that have been specially constructed, converted, and/or chartered for this purpose (Budd and Ison, 2017). Air freight can represent an important additional revenue stream for passenger airlines. Indeed, many of the world's major carriers accept freight on their passenger services, either as a by-product of their passenger provision or as a joint product in which both passengers and freight are equally important, and some operate dedicated freight-only aircraft alongside their passenger fleet. Alongside the passenger airlines are freight only specialists who operate dedicated freight aircraft. The final type of operation are integrators, such as DHL, FedEx, and UPS, who specialize in end-to-end journeys using dedicated fleets of road vehicles and aircraft.

In addition to the type of aircraft and nature of the operation, a key difference between passenger services and freight is that passenger demand is bidirectional and, generally speaking, equal numbers of passengers want to travel from A to B as from B to A. The same is not true of freight, which only moves from its point of production to its point of consumption. The unidirectional nature of freight demand (which is often referred to as the “back-haul” problem) has important implications both for airline operations and practices of marketing, as the return sectors are often not commercially viable. In response, air freight operators may perform triangular or multileg global itineraries to maximize their returns and minimize low loads. This schedule offers commercial advantages to the airline but it may also increase total trip duration and lower the number of direct point-to-point flights that are performed.

Owing to the diverse and demanding nature of the global market it serves, the provision of air freight services is complex and dynamic and the array of activities that are performed represent a challenging prospect for marketing, not least because the behavioral decisions of customers are based not on personal subjective factors, such as in-flight cabin comfort and customer service, but on price, punctuality, reliability (also known as “flown as booked” performance), flight frequency, and efficiency.

The Evolution of Airfreight Marketing

In the early decades of commercial flight in the 1920s and 1930s, high value freight, including diplomatic bags, bullion, and personal effects, was routinely transported on aircraft, but the volumes were small and air freight only accounted for a fraction of the world’s trade by volume. The introduction of larger passenger aircraft from the mid-1940s onwards not only transformed the range (i.e., nonstop distance) that could be flown, but also increased the airlines’ capacity for transporting freight. This presented a challenge. The airlines had newfound supply (in terms of the freight carrying capacity of the new aircraft), but there was relatively little demand, as airfreight services were often considered prohibitively expensive when compared to conventional forms of surface transport and general awareness of the availability of such services among business and the general public was low. The airlines’ marketing challenge was thus to raise awareness of the existence of air freight services and stimulate demand for them by emphasizing the commercial advantages of shipping long-distance freight by air rather than by road, rail, or sea.

One of the principal benefits air travel afforded was its superior speed and its ability to deliver freight consignments over medium and long distances far faster than was previously possible. The early air freight marketing campaigns that were run by the airlines thus emphasized the time savings that could be achieved by air and related this to first mover advantage by stressing that companies who used air freight could reach their consumers quicker than their competitors. There was, however, the issue of cost and door-to-door delivery. It was undeniable that air freight services were more expensive, mile-per-mile, than conventional modes. The airlines thus had to convince potential customers that the additional cost represented good value for money as air freighting enabled them to deliver their products to market sooner. This was deemed particularly attractive for producers who needed to ship time critical and/or perishable commodities. The challenge of providing door-to-door pick-up and delivery was quickly addressed through the provision of integrated courier services who would transport goods from their point of origin to the departure airport and then, on landing, to their ultimate delivery address.

The ability to transport freight around the world by air in this way has both been a driver of, and in turn been driven by, changes in global industrial strategy, the rise of overseas manufacturing facilities and practices of outsourcing and just in time production techniques that demand the rapid and routine international movement of goods and consumer products.

The Scope of Contemporary Airfreight Services

Today, access to safe, secure, and reliable airfreight underpins the international supply chains of many of the world’s largest companies operating in the biotechnology, pharmaceutical, aerospace, electronics, fashion, financial services, and entertainment, sports, livestock, humanitarian, and food production sectors. Much of this activity requires the time critical shipment of precious and/or perishable commodities across international borders and may require specific handling, tilt protection, and/or cool chain protection at all stages of the journey.

The types of commodities that are transported by air are many and varied and range from the routine transport of hazardous materials for the chemical industries to live vaccines and drugs for the pharmaceutical and medical sectors, and from live crustaceans and shellfish to racing cars, consumer electronics, and fast fashion items. Every consignment has particular needs and places exacting demands on air freight providers. The transshipment of valuable commodities, including works of art, for example, requires customized packing, handling, and security. The movement of live animals requires specialist handling and in-flight support to ensure their safe arrival. Vaccines and perishable food require temperature-controlled conditions to prevent them from being spoiled. In every case, the consignments need to be accompanied by accurate and valid airway bills and documentation. Yet in addition to routine shipments, air freight providers must also have the capacity and flexibility to respond to emerging contingencies and react to supply chain disruption that follows service interruptions in other transport modes. In order to examine the nature and complexities of air freight marketing, the fifth and sixth sections detail the service attributes and media that are used by airlines and then airports to market air freight services.

Marketing Airline Airfreight Services

It is apparent from the previous sections that air freight services exhibit distinctive characteristics compared to passenger services. One of the key features that differentiates air freight marketing from conventional air passenger services marketing is that air freight companies can only market their services to customers (i.e., people who take decisions about how freight travels) and not consumers (because they are not actually traveling on the flight that has been purchased). This has important implications for marketing practice, not least since there is no potential for consumers to generate or cocreate marketing content on blogs, review sites, and social media platforms. As a result, air freight marketing relies on a particular set of attributes which manifest themselves in the marketing copy employed by airlines.

One of the ways in which air freight marketing activities seek to create awareness of their products among the target market, influence purchasing behavior, and engender brand loyalty is through printed advertisements which are published in the specialist trade press. One of the challenges of using this form of print media is that the advertisements are seen in close proximity to competitor offerings and so the message must be clear and carry a corresponding appeal. [Budd and Ison's \(2015\)](#) content analysis of the air freight advertisements published in dedicated air freight trade publications revealed that air freight is marketed using five key attributes.

The first of these attributes is connectivity and seamless global flight with advertisements typically emphasizing the geographic extent of an airline's freight network. Such advertisements often use rhetorical devices, including images of the earth from space or abstract representations of the globe, to convey notions of a world that is seamlessly interconnected by freight services. Such images are often accompanied by text, which describes the number of cities, counties, and continents the airline (and, if relevant, its alliance partners) serve. An advertisement in 2018 for Emirates SkyCargo promotes the carrier's "intricate global network of over 250 seamless cargo connections," which "enables us to link your business to the world," while [Air Canada Cargo \(2019\)](#) suggested that, with them, the "entire world is within reach" courtesy of the 450 destinations on six continents that they serve. In some instances, advertisements focus on the connectivity that is provided by the airline's principal operating hub(s) and the speed with which shipments can be dispatched to multiple destinations. This focus on geographic connectivity has clear parallels with the marketing copy that is employed by passenger airlines, although the airports that are served by freight may be different from those used by passenger services.

In addition to promoting notions of seamless global connectivity, a second theme that is evident in air freight advertisements relates to the capacity and capability of the airline in question, as well as its ability to customize its service delivery to meet specific customer needs. In this context, capacity can be described both in terms of the payload weight or volumetric capacity (expressed in tons or number of unit load devices (ULDs) (ULD is a metal container that is loaded into the main deck or hold of an aircraft that contains multiple small freight consignments.) that can be accommodated) and also the airline's ability to accept irregular or outsized shipments. Images of railway locomotives, racing cars, endangered animals, and stage sets for major entertainment events may be depicted to stand proxy for the range and diversity of consignments that the airline can convey. For example, in an advertisement in 2019 announcing the inauguration of two new Boeing 777F aircraft into service, Turkish Airlines Cargo division stated that "Now, you can reach to more countries [sic] than any other airlines in the world with our long haul 2 new Boeing 777F planes with 102 tons capacity," while [SWISS World Cargo \(2019\)](#) promoted the fact that "This year we delivered a world-famous painting custom packaged in airtight conditions from Shanghai to Zurich and then onwards to a museum in Bern"

The third attribute is convenience, as it pertains both to freight consigners and end users. This attribute is typically expressed in terms of the frequency and intensity of freight flights, but also the possibility of employing door-to-door pick-up and delivery using fleets of dedicated road vehicles. "With our frequent flights and logistics know-how we've got your business" back ([Southwest Cargo, 2017](#)). Convenience also extends to the ability to track consignments in real time using a dedicated website or app to provide reassurance that the freight is being flown as booked: "Around the World in One Night. From Premium capacity allocation and service-level guarantee to GPS tracking, 24/7 monitoring and clearly visible pink wrapping, your parcels are delivered with care" ([Delta Cargo, 2018](#)).

In addition to promoting the connectivity, capacity, and convenience of air freight, a fourth set of advertisements emphasize the *care* that will be afforded to a customer's products, particularly those that demand specialist handling, enhanced security, or cool chain capabilities. Accompanying a photograph of a hand holding a delicate porcelain vase, [Qatar Airways Cargo \(2019\)](#) promise that "Whatever your cargo, you can trust us to carry it with as much care as you do" while [Thai Cargo \(2019\)](#) employed an image of a fresh fish and the caption "Keep it Ocean Fresh Across Continents. [Thai] employs an end-to-end cooling system to ensure freshness for temperature sensitive goods and perfect delivery to recipients at every destination." Arguably among the most demanding freight consignments are those for the medical and pharmaceutical industries. [Alaska Air Cargo \(2019\)](#) promoted the fact that "We ship medical items, including lab samples, supplies and live organs overnight to more than 100 destinations in North America."

Unlike the majority of passenger services which tend to operate during the day, air freight services are often scheduled to meet the demanding next-day delivery requirements of consumers and just in time manufacturing systems. The final attribute identified in the advertisements is speed and 24-hour service that stresses that, irrespective of the local time, the company will keep the freight moving. In every case, the aim is to convey the notion that the company is capable, professional, trustworthy, and reliable.

Marketing Airport Airfreight Services

In a highly competitive marketplace, it is not only the airlines that have to market their services. Airports too must compete for custom and the marketing they undertake aims to attract new airlines and routes by stressing the competitive advantages, both to

potential airline operators and air freight forwarders, of conducting business at the facility (Halpern, 2018). Freight airlines and freight forwarders have particular requirements with respect to the provision of ground handling services, the speed and availability of customs checks and border inspection posts, specialist freight handling, storage and processing equipment, and the availability of warehousing space adjacent to the airfield. The marketing of air freight services by airports usually seeks to provide information about existing capabilities and/or investment or expansion potential. Airports may utilize a range of media to market their services. This includes, but is not limited to, corporate event sponsorship, exhibiting, conference attendance, giveaways, and targeted print advertising. As with the air freight marketing copy that is produced by airlines, five key attributes can be identified in the printed material that is produced by airports.

The first of these is capability, with the advertisements stressing that the airport can handle a wide range of goods, from temperature controlled warehouses to e-commerce delivery. Accompanying a montage of images which included a panda, a helicopter, a bunch of fresh tulips, a framed painting, and a piece of fresh cheese, Changi Airport Group in Singapore asked "What makes us one of the world's most trusted cargo hubs: our capabilities."

The second attribute is capacity. In these adverts, the airport operator may seek to reassure potential airlines and freight forwarders that the facility can meet both current and future needs in terms of runway capacity, operating hours, stand space, warehousing, and surface access. A 2019 advert for Miami International Airport, for example, promoted the fact that the facility had no slots, curfews or delays that could inhibit the movement of freight.

The third theme that is evident in the printed advertisements is convenience, both in terms of proximity to major cities and local markets and also easy and reliable connections to the local and national road (and rail) network. The co-location of other freight firms on and around the airport was the fourth marketing point as the co-location of specialist freight handling providers and a local critical mass of expertise appears to be important in attracting new custom.

The final attribute concerns control or the security of goods at the airport. Such advertisements may use images of CCTV cameras and remote monitoring devices to emphasize the security protocols that are enforced and/or the range of secure landside and airside warehousing that is available to potential customers. These attributes are, of course, not mutually exclusive and advertisements may feature two or more of these themes.

Marketing Air Freight Services Using Sponsorship and Giveaways

A further way in which air freight services are marketed by both airlines and airports is through giveaways and corporate sponsorship. Giveaway items can be useful in promoting goodwill and raise customer awareness but they need to be carefully considered and controlled to reinforce the company brand. Ideally, they would be robust practical or fun items. Examples of giveaways include branded pens, lanyards, key fobs, rulers, USB sticks, memo blocks, and sticky notes or items such as branded model aircraft. In every case, the giveaway seeks to raise awareness of the brand in question and reinforce the message that the services that it supplies are useful, dependable, and reliable. There is also marketing value from supplying specialist services at or below cost price, particularly if this supports the company's CSR (corporate social responsibility) agenda. Examples of such practice might include transporting captive bred or rescued endangered animals to release sites in the wild and engaging in postactivity marketing to demonstrate the care, capacity, capability, and compassion that has been shown. Airlines and airports may also use event and/or venue sponsorship or naming rights to raise awareness of their brand and convey their corporate values. Typically, this may involve partnering with a particular charity or nongovernmental organization, sponsoring an event, conference or symposium, or paying for naming rights for sports stadia or major cultural events.

Future Challenges

Although it is difficult to speculate on the future for airfreight marketing, it is reasonable to assume that recent key trends will continue into the short to medium term. In a competitive operating environment, airlines and airports will continue to need to effectively market their services to existing and potential future customers. The key issues facing the sector include: overcapacity and low yields; the impact of volatile fuel prices; fluctuations in global economic activity; the introduction of more stringent environmental regulations and moves to "decarbonize" the economy, changing consumer priorities and the introduction of new aircraft technologies. The key challenges for air freight marketing are thus being able to anticipate, identify and meet the changing needs of shippers and consumers, while deriving a profit from the international transport of freight by air.

Introduction

“The hype over commercial drones is, so far, largely just that. [. . .] widespread deliveries by drone are not yet a reality, neither by Amazon nor by any other company. Regulatory thickets, technical complexity and the public’s skittishness have proven to be formidable hurdles. [. . .] But that doesn’t mean there’s likely to be a drone-free future” (Rosen, 2019). This assessment describes the perceived situation of drone use in logistics in early 2019.

A lot of speculation about the potential of drone use in freight transport is published by different stakeholders. While public media mostly speculates about drone use from a qualitative point of view, some consultancy companies even attempt quantitative forecasts. Pricewaterhouse Coopers LLP for instance stated in 2018 that by 2030 “cost reductions and efficiency improvements from drone usage will feed into an increase of 3.2% in ‘multi factor’ productivity across the UK economy, and contribute to considerable GDP uplifts in many industries . . . ” which include “ . . . £ 7.7 bn in wholesale, retail trade and food services . . . ” (PwC, 2018, p. 3). They also estimate that 11,008 drones will be used in the “transport & logistics” sector in the UK skies by 2030 (PwC, 2018, p. 16).

Shippers as, for example, Amazon or Walmart (FAZ, 2019), as well as transport companies like DHL or UPS have been and still are technically testing air and ground drone deliveries. Still, only a few—Amazon probably the most prominent of them—have actually announced drone delivery services.

Classification of Drones by Mode and Size

To discuss drones and their developing role in freight transport, it is necessary to first roughly categorize the multitude of currently developing drone types. From a logistics point of view, they can roughly be categorized by transport mode (air vs. ground) and by size (small, medium, and large). Table 1 shows a rough overview of typical representatives of this scheme.

Table 1 Types of freight drones

Mode→ Size ↓	Air drones or unmanned aerial vehicles (UAVs)	Ground drones or automated guided vehicles (AGVs)
Small (up to parcel size)	(a1) Small UAV  For example, by EmQopter GmbH (www.qopter.de)	(b1) Small AGV  For example, by Starship Technologies LTD (www.starship.xyz/kit/)
Medium (up to pallet size)	(a2) Medium UAV  For example, by DLR (Deutsches Zentrum für Luft- und Raumfahrt e. V. DLR)	(b2) Medium AGV  For example, by SSI Schäfer (SSI SCHÄFER)
Large (pallet size plus)	Unmanned airplanes	Unmanned trucks

This scheme is quite rough with respect to the size scale—still, one can assume that a *large* drone can transport items exceeding Euro-pallet size, a *medium* drone items up to Euro-pallet size, and *small* drone items up to parcel size. Small air drones can be subcategorized, for example, in accordance with the upcoming EU-drone-flight regulations which most probably will differentiate the total weight categories: –250 g/–900 kg/–4 kg/–25 kg. This article focuses on small and medium drones.

Logistics Use Cases

In general, one can assume that air drones are an interesting option in DDDD (dull, dirty, distant, and/or dangerous) transport environments.

In *intra-logistics*, ground drones (small, medium, and large) have successfully been used for decades, where they are known under the name of autonomous ground vehicles (AGVs). Whereas ground drones usually are the dominant technology in intra-logistics, air drones have started to be seen in niches—for example, if facilities are separated by public roads which need to be crossed.

In *extra-logistics* there are at least three distinct use-case clusters: emergency logistics, rural logistics, and urban logistics. It is difficult to predict how successfully drones will be used in these clusters, as not only technical aspects are to be considered, but political will (with respect to noise emissions, air traffic regulations, energy consumption, etc.) on the one side and lobbyism on the other side will also be important decisive factors. Focusing on technical top-level aspects (existence of infrastructure, energy consumption, and noise emissions) one can derive the following conclusions:

1. In *emergency logistics*, where road transport infrastructure is damaged (e.g., after flooding or after earthquakes) the use of air drones shows great potential, to get the goods to the needy in due time.
2. In *rural logistics*
 - a. the lack of dense road infrastructure together with

- b. the absence of dense population (which will oppose air-drone noise emissions), are two facts which support the speculation that the use of air drones is more promising than the use of ground drones. Here, the possibility of air drones to take shortcuts (e.g., to cross a river or a mountain range) can also compensate for their higher energy consumption.
- 3. In *urban logistics* the use of ground drones seems more promising than the use of air drones, because
 - a. sufficient road infrastructure is available
 - b. air drones need more energy than ground drones (because they need energy to be kept airborne throughout their journey), and
 - c. one cannot shield residents from noise from earlier.

For urban as well as for rural commercial freight transport, both ground and air drones currently still have to face the lack of payload standardization. Today, this lack of standardization leads to a multitude of incompatible infrastructures for loading and unloading of the drones. One may speculate that once the payload dimensions become standardized (as, e.g., today in the industry-standards within the KEP business) and a standardized infrastructure for loading and unloading of drones is established, the use of drones for freight transport may get a boost.

Another factor that promotes the use of drones is their potential to substitute for human drivers and/or couriers. Thus, an increasing use of drones may help to reduce costs for last mile transport while simultaneously low-income transport jobs in last mile delivery face the threat of being substituted by drones.

As of today, *drone use cases* are emerging in CEP-logistics (see, e.g., Amazon Prime Air, DHL, UPS, etc.), food home delivery (see, e.g., Domino's, UberEats, Wing, etc.), and in medical and disaster logistics (see, e.g., ApoAir, QuiQui, Wingcopter, Zipline, etc.).

Loading and Unloading Infrastructure

As all drones for freight transport need to be loaded and unloaded, the relevant loading and unloading infrastructure is relevant for the usability assessment of a drone. Whereas manual loading and unloading is almost always an option, this also is the most cumbersome, slowest and most expensive way to handle cargo. Thus, automated or semiautomated loading and unloading are important for the successful use of drones in transport logistics.

The loading and unloading infrastructure can either depend on handling devices mounted on the drone or on stationary devices at each loading and unloading point. The main options for loading and unloading of small drones are summarized in **Table 2**.

This multitude of handling options calls for standardization efforts. (Note that the extreme success of worldwide ISO-container transport was and is based on container size standardization and container handling standardization by means of corner castings and twist locks on spreaders.) As long as this standardization is not achieved for drones, this lack of standardization will reduce handling efficiency as well as the commercial potential to use freight drones.

Reach and Bimodal Approaches

Even though drones can be operated by combustion engines too, this article shall focus on electrically propelled drones, because on the one hand electric propulsion offers the option to use energy generated by solar, wind, or hydro power, and thus does not necessarily add to global CO₂ emissions, and on the other hand it usually produces less noise.

The reach of electrically propelled ground and air drones is limited by their battery capacities. However, the limited reach of ground and air drones becomes a less important factor, if they are used in a multimodal conceptual setting. In such a setting, the main transport leg is conducted by larger vehicles (e.g., vans), whereas only the last transport leg is carried out by means of a drone (**Table 3a1** and **b1**).

An alternative option to expand the reach of air drones is the concept of hybrid UAVs that have wings as well as copter engines (**Table 3a2**). Hybrid UAVs can operate in a copter or hover mode for takeoff, briefly go through a transition mode into a cruise mode for most of the mission, and return to copter mode for landing. In cruise mode the wings help to carry the drone weight, and thus can cover longer distances than sheer copter drones with identical batteries.

An alternative option to expand the reach of ground drones is the concept to co-use public transport infrastructure (**Table 3b2**). Especially at night, when trams and subways usually do not operate, they could be used to transport ground drones instead of passengers, and bring them to their last mile operation area without significant exhaustion of the drone batteries. The only requirement for this infrastructure co-use is a level access to the trains and the technical ability of the ground drones to use elevators and/or escalators.

Table 2 Selected types of drone loading and unloading devices

Technology	Active stationary devices			Passive drone mounted device	
(1) Horizontal handling	(1a) Active rolls, (1b) pushers, (1c) tilting ramp			Loading bay	
(2) 3-dimensional handling	(2a) Robot arm, (2b) spreader and twist locks			Loading bay	
(3) Manual handling	(3) Humans			Loading bay	
(1a)	(1b)	(1c)	(2a)	(2b)	Legend
Technology	Passive stationary device			Active drone mounted devices	
(I) Horizontal handling	Loading dock			(Ia) Active rolls, (Ib) pushers, (Ic) tilting floors	
(II) 3-dimensional handling	Loading dock			(IIa) Robot arm, (IIb) spreader and twist locks, (IIc) trap door	
(Ia)	(Ib)	(Ic)	(IIa)	(IIb)	(IIc)

Regulations and their Commercial Implications

The use of air drones in freight transport is subject to new regulations, which are currently developing. Worldwide regulations are significantly inhomogeneous. In the EU, a master plan for air traffic management (ATM) has been published and is being updated. Within this process, a “roadmap for the safe integration of drones into all classes of airspace” (Guillermet, 2018) has been released by the project group SESAR. A new drone regulation is scheduled to be issued in 2019. The key ideas of this regulation to come are:

- Distinction of different risk categories C0-C4 which are mostly dependent on total drone weight (–250 g, –900 g, –4 kg, –25 kg), but also include other factors such as speed.
- Defined non-flight zones (especially over airports, industrial plants, public authorities, private ground, nature reserve areas, human crowds, and over emergency response efforts).

Depending on the EU drone risk category, different regulations apply with respect to the minimal distance to people during operations, drone identification, certified drone operator skills, maximal altitude, and the need for a certified authorization of use.

In the United States, the use of air drones for commercial reasons is regulated by the Small Unmanned Aircraft Rule (Part 107 of FAA regulations) (FAA, 2018), which also includes rules for maximum weight, maximum speed, maximum altitude, drone identification, operator skills, etc.

However, there are other aspects of the different worldwide regulations that have a significant influence on the commercial use of air drones, for example:

Table 3 Options to expand the reach of drones

Air drones	Ground drones
(a1) Vehicle-based air drone  Vehicle-based air drone concept of Dropney: truck with onboard rotating parcel magazines and drone magazine (http://dropney.com/showreel/)	(b1) Vehicle-based ground drones  Mothership concept of Daimler and Starship: van with goods magazine and ground drones (https://www.daimler.com/innovation/specials/future-transportation-vans/paketbote-2-0.html)
(a2) Hybrid drone with cruise and hover mode  Use of a hybrid drone with cruise and hover mode for transportation of medication (here in Vanuatu) (www.wingcopter.com)	(b2) Co-use of public transport  First ideas to co-use public transport for logistics purposes are explored. This generic concept can be combined with ground drones (www.logistiktram.de)

- Visual line-of-sight (VLOS)—that is, the operator needs to be able to directly see the air drone during operation. Where this rule applies, it prohibits remote air drone operations, as well as autonomous flight modes outside the vision range of the operator on site.
- Beyond visual line-of-sight (BVLOS)—that is, the operator does not have to be able to directly see the air drone during operation.
- 1:1 Operator control—that is, no person may act as a remote pilot in command for more than one unmanned aircraft operation at one time. Where this rule applies, each air drone needs a dedicated drone operator, and this significantly increases the costs of operating drones.
- Daylight operations only—that is, the drones must not operate in the dark. This regulation limits the use of air drones significantly, as air drone logistics service providers will either have to shut down their services at nightfall, or they need a non-air-drone-based fallback delivery concept.
- Must yield right of way to other aircraft—this generic regulation implies that there are rules for “right of way” and rules on how to yield correctly—these rules must be known to the drone operator and they must be supported by the relevant autonomous flight modes.

From today’s point of view, it seems likely that air drone regulations will undergo several adjustments in the short- and medium-term future, as lobbyists will ask lawmakers to lower restrictions, whereas voters may ask for additional restrictions for noise, privacy, and damage protection once air drones become more widely used.

Selected Safety and Security Issues

Safety and security are essential for the commercial use of drones in freight transport. Whereas safety issues focus on potential harm to humans (i.e., recipients as well as third party bystanders) in this context, security issues focus on potential harm to the transported goods. Safety and security issues can also be categorized by “on route” (while moving) and “on site” (during loading and unloading).

Table 4 Selected safety and security issues

Mode→	Air drones	Ground drones
Safety on route	⚡ <i>Crash</i> due to collision with moving objects, stationary objects, weather conditions, or due to energy exhaust ⇒ Regulations for flight over people ⇒ Air-drone parachute 🚨 ●●● High	⚡ <i>Stop</i> due to collision with moving objects, stationary objects, weather conditions, or due to energy exhaust ⇒ General traffic regulations ⇒ Active signaling (flashing warning lights) 🚨 ●○○ Low
Safety on site	⚡ <i>Rotating rotors</i> hurting persons ⇒ Caged rotors ⇒ Presence detectors ⇒ Cargo drop 🚨 ●●● High	(No similar issues due to small weight and slow speed of ground drone) 🚨 ○○○ None
Security on route	⚡ <i>Air piracy</i> by catcher drones or by redirecting software hacks ⇒ Permanent monitoring 🚨 ●○○ Low	⚡ <i>Road piracy</i> by manual theft or by redirecting software hacks ⇒ Permanent monitoring 🚨 ●○○ Low
Security on site	⚡ <i>Theft</i> ⇒ Identification check prior to unlocking 🚨 ●○○ Low	⚡ <i>Theft</i> ⇒ Identification check prior to unlocking 🚨 ●○○ Low

⚡: Hazard; ⇒, countermeasure; 🚨○○○, potential commercial damage in event.

These issues as well as possible countermeasures and a rough estimate of their potential commercial damage potential are shown in **Table 4**.

The qualitative assessment of potential commercial damage in the safety or security event in **Table 4** is based on the following ideas. First, if humans are harmed, this usually induces significant legal settlement costs, especially compensation payments for the victims. If transported goods are harmed, the *settlement cost dimensions* are smaller by magnitudes compared to harmed humans. Second, usually incidents where humans are harmed cause a significant *reputation problem*, whereas incidents where goods are damaged or lost often can be settled without great public attention. Third, ground drone transport problems can be considered to be *known problems* as there exists decades of experience from other ground transport executions. However, air drone transport problems are rather unknown, because air drone traffic is new and not yet widely used. Fourth, the magnitudes of piracy and theft issues are similar for air and ground drones.

Noise Emissions

Especially in urban logistics, noise emissions play a big role. Whereas huge sums of money are invested to shield citizens from road-and/or rail-noise emissions, there simply is no technical way to protect citizens outdoors (e.g., in their garden or on their balcony, or citizens who want to enjoy fresh air through an open window) from air noise. While some flats facing busy streets are already overexposed to street noise, often other flats in the same building provide the noise-wise rest and peace of an enclosed atrium. Thus, there are three options:

- Low-altitude corridors: Should air drones be limited to flight corridors over existing streets below average roof height, where they would not add to the noise pollution of currently non-noisy living quarters, but they would significantly add to the noise exposure of higher floor flats. At the same time, within this corridor option air drones would lose their potential to use beelines as route trajectories, and thus save on distance traveled.
- High altitude corridors: Should air drones be limited to flight corridors over existing streets above average roof height, where they would add to noise pollution of currently non-noisy living quarters—the higher they fly, the higher the noise emission radius (and the lower the emitted noise level per unit). In this option the beeline advantage would also be lost.
- No corridors: Should air drones be permitted to fly all possible beelines without corridors, such that their noise emissions would potentially cover all areas. In this case, the highest possible flight altitude (without infringement of current air traffic) would minimize noise emissions for citizens, whilst creating a permanent background hum noise from earlier (if many drones are airborne simultaneously).

Within all three options, air drones would create local noise during takeoff and landing, which freight recipients might accept, but neighbors may not. Ground drones on the other hand do not add to the noise problem, as on the one hand they produce almost no noise (compared to air drones) and on the other hand they share the infrastructure of today's noise-emitting traffic.

Critical Discussion of Air Versus Ground Drones

Both drone types share the potential that (if operated autonomously) they can operate *without a driver*, who is a significant cost factor in last mile logistics. Both lose this potential if regulations require a 1:1 full-time operator-drone surveillance. It is likely that ground drones will be exempt from this 1:1 regulation because they could “stop and wait” in critical situations (i.e., the default security mode in ground traffic) until a 1:many operator can take care of the situation. To achieve an exemption from 1:1 full-time operator surveillance for air drones seems more difficult from today’s point of view.

The one advantage of air drones is their potential average *cruise speed*. Whereas ground drones would most probably operate at pedestrian speed on sidewalks, at cyclist speed in bicycle lanes and at average traffic speed on roads, air drones could operate at higher speeds. This advantage is reduced, if, due to reach expansion requirements, a bimodal transport (e.g., truck and air drone, or subway and ground drone) is required.

The other advantage of air drones is their independence from road infrastructure, which renders air drones especially valuable for emergency freight transport.

For most other aspects, such as energy costs, noise emissions, safety, and sustainability, ground drones seem the superior option to execute the last mile freight transport—especially in urban environments.

Open Issues

There are a number of open issues that need further research and further experience from first operations. These issues are the following:

- Risk assessments are needed for different use cases. As a first step, these risk assessments will need to be based on assumptions and test cases, but they will need to undergo revisions as soon as significant experience from real-life operations is available on a larger scale.
- Drone traffic regulations are currently being developed by lawmakers. Similar to the risk assessments, this lawmaking process will constitute first regulations and later modified regulations based on the feedback from different stakeholders (shippers, drone operation service providers, customers, citizens, and lobbyists). One interesting aspect here is the willingness to open up existing public transport infrastructure for co-use by ground drones.
- Sustainability assessments for a wider use of drones are needed soon. Whereas technical innovations may reduce a few percent of energy consumption rates or noise emission rates, they do not change the big picture. Is it wise to propagate air drones for urban convenience services while humankind faces global warming and mass extinction of species? Therefore, further sustainability research is needed as well as political will to take actions.
- An interesting and, most probably, the decisive question in assessing the future of commercial freight drone operations is: will freight drone business models be profitable? This question is strongly dependent on the relevant use case, as well as on a multitude of cost factors (required investment, HR costs for operators, energy costs, etc.) and on regulations, which may influence the cost factors, and prohibit or allow business cases.

Introduction

Transporting freight in large trucks is an inherently dangerous activity with the potential risk of a fatal or injury crash causing significant costs as a result of deaths, injuries, property damage, and cargo losses. In fact, throughout the period 2010–17, there has been a significant increase in the United States in the rate of large truck involvement in fatal crashes per 100 million vehicle miles from 1.2 in 2010 to 1.6 in 2017, an increase of 33% (Fig. 1) (FMCSA, 2017). There has also been an even more dramatic increase in the large trucks involved in injury crashes per 100 million miles from 20.3 in 2010 to 38.1 in 2016, an increase of 89% (Fig. 2) (FMCSA, 2019). These significant increases contrast sharply with a continuous decline in both trucks involved in fatal and injury crashes per 100 million miles between 1975 (the first year of recorded truck crash and injury data by the Federal Motor Carrier Safety Administration [FMCSA]) and 2009. Each of the 4237 fatal truck crashes in 2017 involved an economic cost of \$7.2 million or a total cost of \$30.5 billion.

Recognizing the inherent danger associated with large trucks operating on the nation’s highways, it is important to understand the obligations for shippers, brokers, and third-party logistics providers, the users of motor carrier transportation services, to ensure that the carriers they select can, in fact, conduct their operations in a safe and efficient manner. Over the last 15 years, the issue of shipper, broker, and third-party logistics provider responsibility has been litigated in civil cases based on truck crashes that resulted in fatalities and/or serious personal injuries. These cases litigated in state and federal courts have attempted to define the scope of responsibility for users who select individual motor carriers to transport freight on public highways (e.g., Schramm v. Foster et al., 2004; Jones v. C.H. Robinson Worldwide, Inc., 2008).

Prior to examining specific aspects of broker, shipper, and third-party logistics provider responsibility in the carrier selection process, it is necessary to examine the dynamics of the trucking industry structure as well as the role of the FMCSA in providing the user community with near real-time data regarding the safety performance of individual motor carriers. Both of these topics need to be explored in order to establish the context for assessing the user community responsibility in the carrier selection process.

Dynamic Structure of the Trucking Industry in the United States

Congress essentially deregulated the industry with the passage of the Motor Carrier Act of 1980. The Act created a process allowing for entities to obtain a DOT number quite easily, by completing a registration form where a declaration is made with respect to the type of operation requested (interstate or intrastate), as well as the commodity segments intended to operate in (general freight, refrigerated cargoes, etc.). Once the entity or carrier received a DOT number, the process of obtaining an operating certificate is also straightforward involving the payment of a \$300 fee, the completion of an information form and safety certification, proof of insurance, and the designation of a process agent. These minimal requirements to initiate a valid motor carrier operating business have resulted in an explosion in the total number of interstate motor carriers. In fact, the total number of carriers stood at over 500,000 in 2019. Recognize, however, that the majority of the interstate motor carriers with valid operating authority own and operate a small number of power units. In fact, the overwhelming majority of the 500,000 carriers own fewer than five power units, with the majority owning one or two power units (Cantor et al., 2013, 2017).

The industry structure has a profound impact on motor carrier safety as well as on the responsibility of the user community in the carrier selection process. Previous academic research indicates that a one-vehicle owner-operator who drives for many different employers is likely to have significantly worse safety performance (in terms of both regulatory compliance and crash rates) than would a carrier with larger vehicle fleets and established safety management programs and policies. This makes sense, because there is

Figure 1 Large truck fatal crash rate: 1975–2017. *Source: Analysis Division, Federal Motor Carrier Safety Administration, Large Truck and Bus Crash Facts 2017, March 2019.*

Figure 2 Large truck injury crash rate: 1995–2016. *Source: Analysis Division, Federal Motor Carrier Safety Administration, Large Truck and Bus Crash Facts 2017, March 2019.*

a good chance that a one-person owner-operator will not have the resources necessary to establish internal safety monitoring programs and processes, and to properly train and supervise himself. These findings have important implications for the carrier selection process and the responsibility of the user community in exercising reasonable care in the selection process (Cantor et al., 2017).

FMCSA Motor Carrier Safety Performance Data Initiatives

The FMCSA recognized that with the rapidly increasing number of motor carriers with valid interstate operating authority, it was critical to provide information to the transportation user community about the safety performance of the carriers. Indeed, the

objective of the FMCSA was to provide the user community with ongoing, real-time information regarding the safety performance of individual carriers so that users could incorporate this information in their selection process.

From December 1999 through November 2010, FMCSA provided information about carrier safety performance through the Analysis and Information section of its website. The SafeStat (Motor Carrier Safety Status Measurement System) evaluated carrier performance in four areas (safety evaluation areas or SEAs: driver, vehicle, safety management, and accidents) by scoring carriers on a percentile scale of 1–100, with higher scores indicating poorer safety performance. Carriers with scores above the 75th percentile on any of the SEAs were judged to be “above the threshold” level and subject, therefore, to additional inspections and reviews. In December 2010, the SafeStat system was replaced with the safety measurement system (SMS). The SMS was a finer grained assessment of carrier safety performance. It broke down the Driver SEA into its components (unsafe driving, hours-of-service violations, drug and alcohol abuse, and driver fitness). In addition, the SMS scored carriers on vehicle maintenance and provided a crash indicator. The FMCSA set threshold scores for each of the indicators, labeled in SMS as BASICS (behavioral analysis and safety improvement categories), based on the relationship between each BASIC to future crash likelihood. The threshold scores for unsafe driving, hours-of-service violations, and vehicle maintenance were set lower than the scores for the other BASICS, based on systematic empirical research demonstrating that higher scores on these three BASICS (thus indicating poorer safety performance) were more directly associated with a significantly higher future crash rate. Like SafeStat, SMS tagged carriers as being above the threshold if their percentile scores, in a particular BASIC, exceeded the designated threshold for that BASIC (FMCSA, 2019).

Both the SafeStat and the SMS converted carrier safety scores to percentiles so that carriers with like characteristics (in size or number of safety events) were grouped together for comparison purposes. The basic inputs into both SafeStat and SMS were the results of roadside inspections and “Compliance Reviews.” Each inspection or review included a number of items for assessment. Scores were computed based on the number of violations detected, along with the severity of each violation. Once each carrier was scored based on its accumulation of violations during inspections and reviews, the carrier was assigned to a specific size group. Within each group, carriers were arrayed based on their raw violation score and percentiles were assigned within each group, with the carrier having the fewest violations obtaining the lowest percentile score and the carrier with the most violations obtaining the highest percentile.

The underlying philosophy of FMCSA throughout this period was that with the large number of operating carriers in a deregulated environment, the best strategy for ensuring safe operations on the nation’s highways was to make real-time safety performance data available online so that the user community could incorporate this information as they selected individual carriers. Recognize that both SafeStat and SMS had data sufficiency tests such that carriers with insufficient data regarding inspections or reviews were not scored in the respective systems. Thus, many small carriers, in particular, do not have performance scores.

It is also important to note that separate from SafeStat and SMS, Congress mandated in 1984 that regulators determine the safety fitness of interstate motor carriers through an onsite comprehensive “Compliance Review.” As a result of this review, carriers receive a score of either “satisfactory,” “unsatisfactory,” or “conditional.” Carriers with an “unsatisfactory” result ultimately will lose their operating authority if they do not obtain approval of a corrective action plan. The results of Compliance Reviews continue at this time to be the sole basis for assigning an interstate carrier with a Safety Fitness Rating. FMCSA has resources to conduct a limited number of Compliance Reviews (some 15,000 annually). Thus, the overwhelming majority of carriers operating in interstate commerce have no Safety Fitness Rating, although many of these carriers do, in fact, have an array of scores in the BASICS that are displayed within the Analysis and Information section of FMCSA’s website.

Assessing “Reasonableness” in the Carrier Selection Process

With an understanding of the trucking industry structure and knowledge about the public availability of real-time motor carrier performance available as a consequence of FMCSA’s SMS program, it is important to examine the level of responsibility for shippers, brokers, and third-party logistics providers in the carrier selection process.

There is a consensus that there are three necessary conditions that users of motor carrier services must establish that their selected carriers possess prior to engaging their services. Users of motor carrier services have the obligation to ascertain that their selected carriers have valid motor carrier operating authority, have the required levels of insurance coverage, and do not have a Safety Fitness Rating of unsatisfactory. While these conditions are universally accepted as necessary conditions for selection, the discussion revolves around whether or not these three conditions constitute a sufficient level of evaluation in order to ensure that motor carrier operations on the nation’s highways are conducted in a safe and efficient manner (Corsi, 2018).

Defining Carriers as Independent Contractors or Agents; Assessing Negligence in Carrier Hiring

Many brokers, shippers, and third-party logistics providers have the opinion that the motor carriers whose services they engage are “independent contractors.” As a consequence, the entire burden of complying with FMCSA rules and regulations is up to the carriers themselves. The brokers, shippers, and third-party logistics providers often state in broker-carrier or shipper-carrier agreements that the carrier is obliged to comply with the regulations, but that responsibility, according to the signed agreements, is the sole responsibility of the carriers, themselves. Many brokers, shippers, and third-party logistics providers assert that they have absolutely no responsibility beyond ensuring that the earlier necessary conditions for carrier selection are met.

There are two important challenges to this interpretation put forward by many shippers, brokers, and third-party logistics providers. First, in many situations, the relationship between the shippers, brokers, and third-party logistics providers, and the carriers does not meet the requirements associated with the engagement of an independent contractor, since the users exercise a degree of control over the carriers activities that exceeds the actions normally associated with an entity engaging the services of an “independent contractor.” In many instances, the shipper, broker, or third-party logistics provider arranges the shipment, dispatches the carrier drivers, monitors the freight shipment from origin to destination, requires the driver to call the dispatch at multiple times over the course of the shipment, penalizes the driver for late deliveries, bills the shipper, pays the carrier, and prohibits the carrier from contact with the shipper/receiver. These actions are totally inconsistent with actions normally associated with an entity engaging the services of an “independent contractor.” In these situations, the motor carrier is far from “independent.” The relationship is more properly defined as a “principal-agent” relationship, with the principal directly responsible for the actions of its agent (*Tryg Insurance v. C.H. Robinson Worldwide, Inc.*, 2019).

Second, the viewpoint that shippers, brokers, and third-party logistics providers have no responsibility in motor carrier selection beyond the necessary conditions cited earlier is inconsistent with the obligation of a contractor to use reasonable care in selecting a subcontractor. Indeed, the shipper, broker, or third-party logistics providers can be found negligent if they fail to exercise caution, oversight, or reasonable care in the selection process.

The Legal Battle for Assessing Carriers as Independent Contractors and Determining Negligence in Hiring

Legal disputes have emerged over the last 15 years regarding the issue of whether carriers selected by shippers, brokers, and third-party logistics providers are, in fact, independent contractors or simply the agents of the party who hired them. Equally subject to significant dispute is the question of whether or not the users exercised reasonable care in the selection of carriers, if the carriers were, in fact, considered as independent contractors.

Two seminal cases in this area are the Schramm Case (2005, Maryland) and the Jones Case (2008, Virginia). In both cases, Courts ruled that the broker, C.H. Robinson, the nation’s largest broker, had an obligation to review available safety performance data as part of its carrier selection process. The respective Courts ruled that this requirement was not, in fact, a burden but a necessity. The cases were decided on the basis of negligent hiring of a carrier by the broker involved.

These seminal cases led to a series of additional cases in which plaintiffs sued shippers, brokers, and third-party logistics providers in the aftermath of fatal or serious crash injury cases on the basis either that the carriers were not, in fact, independent contractors but were subject to the control and oversight of the shippers, brokers, or third-party logistics providers, or that there was not reasonable care exercised in the selection process. In fact, the failure to use reasonable care constituted negligence in the hiring of an independent carrier by the shipper, broker, or third-party logistics provider. A number of these cases have resulted in out-of-court settlements between the parties. As a result, from a legal perspective, there is continuing uncertainty about the ultimate resolution of the issue.

Shippers, Brokers, and Third-Party Logistics Providers Seek Relief From Reasonable Care Obligations

In this environment, shippers, brokers, and third-party logistics providers have mounted a concerted effort to obtain relief from any obligation in hiring motor carriers beyond the three minimum standards discussed earlier. The user community launched an extended campaign against the percentile rankings associated with the BASIC scores in the SMS. As a result, Congress in December 2015 passed the Fixing America’s Surface Transportation Act (FAST). This legislation required the FMCSA to remove from the public website percentile scores for each carrier on each of the BASICs. The legislation allowed the FMCSA to continue publishing on its public website each carrier’s underlying scores (called measure scores). As noted, the underlying measure scores were converted in the methodology to percentile scores, after carriers were divided into size groups based on each carrier’s number of safety events (inspections and reviews). The user community had launched its attack with the claim that the SMS methodology was unreliable. In passing the FAST Act, Congress commissioned the National Academy of Sciences/Transportation Research Board to conduct a thorough examination of the efficacy of the SMS methodology. The report concluded that the methodology was sound in its ability to associate high percentile scores with increased likelihood of future crash involvement (*Volpe National Transportation Systems Center*, 2014). However, the report did, in fact, propose that the FMCSA evaluates some alternative methodologies, believed by the authors of the report to have the potential to be more effective than the SMS methodology. The report made no recommendation on whether the percentile scores should be made available once again (*National Academy of and Sciences*, 2017). As of 2019, the percentile scores and the associated threshold warnings are not part of the public website.

The user community as of 2019 were actively pursuing additional federal legislation to establish that the process of carrier selection be based on the necessary criteria discussed earlier with one important change. Rather than using the existing Safety Fitness Rating, based solely on Compliance Review, the user community advocate a far more generous method, resulting in almost all carriers being regarded as satisfactory, as the basis for the third component of the necessary selection criteria. The user community sought this legislation in the hopes of being provided with a legislative basis for relieving them of any obligation to review a carrier’s safety performance data at the level of the BASICs in making a selection decision. Indeed, the nation’s largest broker, C.H. Robinson, has repeated the assertion in numerous court depositions, that it considers absolutely no safety performance data for carriers in their selection process beyond establishing that the carrier has a valid operating authority, proper insurance levels, and does not have an

“unsatisfactory” safety rating (Craig, 2019). The intended legislation will codify a selection process with minimal attention to safety performance of the carriers with an emphasis on necessary, but not sufficient, considerations.

Safety Implications of Minimal Shipper, Broker, and Third-Party Logistics Provider Attention to Safety Performance Matters in Carrier Selection

There are a number of concerns regarding the proposed legislative cover for shippers, brokers, and third-party logistics providers to minimize their responsibility in evaluating and selecting motor carriers for transportation services. First, recognize that the inclusion of a carrier’s safety performance record as a key component of the selection process constitutes a powerful incentive for carriers to maintain an excellent safety record by avoiding violations of FMCSA regulations during inspections and reviews. Carriers have recognized, beginning with the introduction of online safety performance data with SafeStat, that their poor safety performance record will have a direct impact on future business opportunities, especially among the users who place a high value on securing safe carriers. Indeed, some shippers, brokers, and third-party logistics providers would not engage the services of carriers with multiple BASIC values exceeding FMCSA established thresholds. With the removal of the BASIC percentile scores and above-threshold indicators from the FMCSA website, it can certainly be argued that it is more challenging for users to incorporate a carrier’s safety performance record into its selection algorithm.

Second, recognize that, in the current environment, many truckload shipments are arranged through internet load boards. Shippers frequently contract with brokers/third-party logistics providers to transport specific loads on their behalf for a specific freight rate. Brokers/third-party logistics providers will fulfill the particular shipper request by engaging the services of a carrier with whom the broker/third-party logistics provider has an ongoing relationship (formalized in a broker–carrier agreement) or by posting the load on an internet load board. Posting the load elicits bids from carriers to provide the requested transportation services. The broker/third-party logistic provider’s business model is based on the margin between the amount they have contracted with the shipper for the designated transportation services and the amount bid by the carriers to transport the load in question. The lower the carrier bid for the transportation services, the higher the broker margin. This system creates an incentive for the brokers to select carriers offering the lowest bid. Previous academic research has demonstrated that there is a direct link between carriers under financial stress (likely carriers consistently submitting low bids in response to broker/third-party logistics postings) who have significantly higher rates of FMCSA violations and crashes (Miller and Saldanha, 2016). Minimizing the responsibility of brokers/third-party logistics providers to incorporate safety considerations in the carrier selection process would only intensify the use of low-bid carriers, likely under financial distress.

Third, the discussion of the dynamic trucking industry structure in a deregulated environment revealed that there are thousands of carriers with valid interstate operating authority who are no more than single-vehicle owner-operators—that is, one-person carriers. Previous academic research has shown that these one-vehicle carriers have significantly worse safety performance than do carriers with larger vehicle fleets and established safety management programs and policies. Indeed, the one-person carriers do not have resources necessary to establish internal safety monitoring programs and processes. Nor do they have the resources to properly train and supervise themselves. Yet, under the current environment, shippers, brokers, and third-party logistics providers want to minimize their oversight of these single-vehicle carriers with respect to safety performance (Cantor et al., 2013). Rather than hiring a carrier with an established vehicle fleet and safety program, engaging the single-vehicle carrier is directly comparable to hiring an individual driver, not a carrier. Allowing shippers, brokers, and third-party logistics providers to equate these single-vehicle owner-operators as carriers and independent carriers as opposed to requiring them to use reasonable care in examining the safety performance of these individuals will have negative safety consequences with respect to crash frequency.

Finally, recognize that if users are successful in obtaining legislation from Congress that restricts the requirements for carrier selection to the minimum levels stipulated earlier (with a new less restrictive determination of Safety Fitness, not tied to the results of a Compliance Review), users must consider that they will still be subject to legal challenges based on the control exercised over the carriers, defining the relationship as that between a principal and its agent, rather than as being defined as an independent contractor relationship. Second, there will remain the issue to determine whether the user exercised reasonable care in the selection process or whether the user was negligent in contracting with a carrier who represented a known risk to the traveling public through its record of safety performance violations and past crashes.

Requiring users to incorporate safety considerations in a carrier selection process, due to the inherent danger associated with motor carrier operations, has been incorporated into the broader concept of a “chain of responsibility,” shared by all parties involved in freight transportation. Thus, Australia has codified the shared responsibility concept that encompasses all parties involved in the transportation of freight from the shipper to the broker/third-party logistics provider to the carrier and, ultimately, to the driver. In the Australian legal environment, each of these entities has a shared duty to ensure that trucking operations are conducted in a safe manner (OECD, 2011).

Conclusion

The trend in higher rates of truck involvement in both fatal and injury crashes since 2010 is disturbing. What intensifies concerns about this trend is the concerted effort by many shippers, brokers, and third-party logistics providers to minimize the role of carrier safety performance in the selection process. There is a clear danger in breaking the “chain of responsibility,” covering shippers,

brokers, third-party logistics providers, the carriers themselves, and the individual drivers to ensure that motor carrier operations are conducted in a safe and efficient manner.

As noted, the increasing reliance on internet load boards for selecting carriers creates an environment that encourages brokers and third-party logistics providers to select low-cost carriers, often carriers who have reduced rates at the expense of safety management programs and practices. Requirements for users to exercise “reasonable care” in selecting carriers represent a powerful counter to ensure that safety receives priority in the selection process.

Furthermore, the changed industry structure has resulted in a large number of single-vehicle, owner-operator carriers. The shippers, brokers, and third-party logistics providers engaging the services of a single-vehicle, owner-operator carrier are, in reality, hiring an individual driver, who requires management oversight to ensure compliance with FMCSA regulations. Shielding shippers, brokers, and third-party logistics providers from the “chain of responsibility” in these cases will further erode truck safety on US highways.

Reversing the recent trend toward higher rates of truck involvement in both fatal and injury crashes requires a greater commitment to enforcing a “chain of responsibility” to ensure that the carriers selected have processes in place that will minimize the likelihood of future serious truck crashes. Efforts to minimize the responsibility of parties in the selection and oversight of carriers are counterproductive to the goal of reducing truck involvement in serious crashes.

The FMCSA should continue to support requirements for interstate carriers to adopt new technologies designed to enhance truck safety (Cantor et al., 2016). The FMCSA requirement for carriers to install electronic logbooks is an excellent example of a regulatory initiative to enhance safety. There is no question that there are rapid advancements in vehicle technology to make transportation operations safer by reducing crash risk. FMCSA should be diligent in examining new technologies that will enhance safety and requiring the industry to adopt those that have a documented impact on truck crashes. The FMCSA has the legislative mandate to reduce truck crashes and should continue in its efforts to be proactive in fulfilling its mission.

Introduction

Logistics costs account for a substantial portion of the overall cost of a product delivered to the end consumers. In some product categories, logistics costs can make up more than 50% of the total cost. It is not surprising, therefore, that companies seek to manage their logistics operations as efficiently as possible. Unless a company operates its own private fleet (such as Walmart, PepsiCo), it must utilize carriers to transport its shipments. Carrier selection is one of the most important logistics decisions a company must make, as the carrier selection decision has a huge impact on a company's strategic, tactical, and operational planning phases.

One can categorize carriers into three classes based on the typical size of the shipments: courier service providers (parcel delivery), less-than-truckload (LTL) carriers, and full-truckload (FTL) carriers. Courier service providers, such as USPS, UPS, and FedEx, deliver parcels of relatively small size nonpalletized packages, which typically weigh less than 100 lbs (50 kg). Courier service providers are mostly used for residential deliveries. LTL carriers generally transport shipments consisting of multiple pallets that do not make up a full trailer, that is, a full truckload. On the other hand, FTL carriers, as the name suggests, dedicate trucks for the shipments they make. It is worthwhile to note that an FTL carrier does not necessarily ship a fully loaded truck because the shipper might prefer to partially fill a truck.

LTL transportation is crucial for the success of many businesses, especially considering the growth in ecommerce. In the United States, the LTL market is somewhere around \$35–\$40 billion (Ozkaya et al., 2010; Bokher, 2018; Robinson, 2018). An LTL shipper refers to a business using the services of an LTL carrier. Considering that there are many LTL carriers available with varying attributes, it is a challenging task to select a carrier for the shipments. Furthermore, the carrier selected will affect the performance of the other supply chain practices undertaken. Therefore, a business needs to be careful in selecting a carrier for its LTL shipments. Prior to discussing LTL carrier selection further, it is important to discuss when a shipper should prefer LTL over FTL shipments.

As noted earlier, the size of the shipment is an important factor to determine the type of the shipment; however it is not the only factor. The frequency of shipments is another key factor. For instance, instead of making weekly LTL shipments, a shipper can consolidate several of its shipments and make monthly FTL shipments. Another factor to consider is the number of different shipments made. Again, a shipper can consolidate several relatively small LTL shipments destined to different locations into one FTL shipment, which would require a truck to make several delivery stops. Such a consolidation of shipments would require coordinating the shipments to different destinations, as this consolidation necessitates common delivery windows (see, e.g., Konur and Geunes, 2019). Furthermore, most LTL and FTL carriers offer discounts based on the size and the frequency of the shipments. Therefore, the shipper should consider consolidation opportunities and carefully evaluate the implied tradeoffs between the frequency and the amount of individual and consolidated shipment options before deciding to use an LTL carrier over an FTL carrier. Moreover, the freight type, shipment budget, delivery time restrictions, and loading/unloading requirements should be considered when choosing between LTL and FTL shipments.

The focus in this chapter is on LTL carrier selection. In particular, we will first discuss the implications of carrier selection in strategic, tactical, and operational planning phases of a supply chain. Then, the factors shippers typically consider in carrier selection for LTL shipments are reviewed. Next, we quantify the impacts of four key factors on the logistics costs and service levels of a company through a stochastic inventory control model. The reader is referred to [Meixell and Norbis \(2008\)](#) for a review of transportation mode choice and the carrier selection literature for other various aspects of LTL carrier selection research.

LTL Carrier Selection and Supply Chain Planning

Effective supply chain management is key to the success of any business. Every planning decision made will have an impact on every stage of a supply chain. Typically, supply chain planning decisions are managed at three levels: strategic, tactical, and operational planning ([Nahmias, 2009](#)). The strategic planning phase consists of long-term decisions, which will be in effect for a relatively long period of time (e.g., 5 year, 1 year), such as supply chain network design, market entry choices, products offered, and manufacturing strategies. For instance, location decisions of production facilities and/or warehouses are strategic planning decisions, as a business will operate such a facility for a long time at the same location. The tactical planning phase consists of mid-term (e.g., quarterly, monthly) decisions such as seasonal promotions, supplier contracting, and inventory control decisions. The operational planning phase consists of short-term decisions, related to weekly or daily operations such as deliveries, routing and loading/unloading operations. LTL carrier selection can be regarded as a tactical or an operational planning decision; however it will have an impact on the performance of strategic planning decisions as well.

LTL Carrier Selection and Strategic Level Planning

Strategic level decisions are crucial for successful supply chain management, since such decisions constrain the tactical and operational planning decisions. LTL carrier selection will be directly affected by several strategic planning decisions. The supply chain network configuration and the market entry decisions of a business are the main determinants of the shipments to be made. Accordingly, a company might need to use LTL shipments and select carriers for each shipment. The performance of a strategic decision made will be affected by LTL carrier selection. In order to efficiently design a supply chain network, a business should account for the implied LTL shipment costs, which means that it should evaluate the available LTL carriers and their attributes for various network configurations. Similarly, in market entry decisions, a business should analyze the feasibility of such entry decisions considering the carriers available to make LTL shipments to various customers in the markets to be entered. While strategic level planning typically does not account for the detailed cost implications of a decision on the mid- and short-term practices, a business should not completely ignore the effects of LTL shipments in their strategic planning.

LTL Carrier Selection and Tactical Level Planning

At the tactical level, the decisions made are not binding for a very long time. However, it is not very easy to adjust the tactical level plans without significant operational changes. LTL carrier selection can be accepted as a tactical level planning decision, especially considering the contracting opportunities with an LTL carrier. Typically, a business can negotiate a relatively long-term contract with a carrier. Such contracts may include conditions on the annual amount of shipments needed to be made by the shipper. Inventory management decisions at the tactical level should be made in an integrated manner with LTL carrier selection. Particularly, inventory control is the key driver of the amount and frequency of the shipments to be made, which are the key factors in deciding which carriers to use. The inventory management literature has focused intensely on joint carrier selection and inventory control decisions. LTL carrier selection should also be accounted for in supplier selection decisions because the selected suppliers will characterize the origin/destination of the required shipments. In addition, seasonal promotions offered by a business might imply significant changes in the shipment requirements, therefore LTL carrier selection should be taken into account in designing seasonal promotions. To this end, while LTL carrier selection itself can be considered as a tactical decision, it should also be integrated with several other tactical planning decisions.

LTL Carrier Selection and Operational Level Planning

Short-term recurring operations are crucial for the seamless supply chain activities of a business. On-time deliveries, material handling operations and inventory replenishment activities have significant cost, as well as service level, implications. LTL carrier selection is, therefore, essential for efficient operational planning. One reason is that the carrier selected determines the transit time and, thereby, when the shipments are estimated to be delivered. Delivery times are critical for both inbound and outbound shipments. Inbound shipment times might affect the production at a manufacturing facility and inventory replenishments at a retail store. Outbound shipment times can make the shipper liable for delayed shipments, considering the just-in-time requirements of the receiving party. Furthermore, the shipment is not just about transportation. A shipment will be loaded and unloaded, and these operations might require materials handling equipment. LTL carriers might offer material handling services in addition to the transportation of the shipments. As such, LTL carrier selection has an impact on many short-term operations, and therefore, available carriers should be carefully evaluated considering various operational implications.

LTL Carriers and Shippers

The two main decision makers about LTL shipments are the carriers and the shippers. The LTL carriers decide on the rates for the services they provide and how they provide these services. The LTL shippers decide on their shipment sizes and which carrier(s) to use. It is important for each party to understand the dynamics of the other.

How Do the LTL Carriers Work?

The main advantage of LTL carriers for a shipper is the cost savings from a shipment that does not justify an FTL shipment. LTL carriers also offer flexibility through alternative schedules, and they can provide additional services such as loading/unloading support. In general, LTL carriers are able to offer such benefits because they utilize economies of scale due to the aggregation of individual demand for their services. Typically, LTL carriers operate on a hub-and-spoke network (Cerasis, 2016). Drivers with small trucks collect the regional demand and carry it to a regional distribution point; the cumulative regional demand is then shipped to a hub; and the hub serves as a cross-dock facility where shipments from different regions are consolidated and dispatched according to their destinations. This consolidation of various requests from different shippers enables the high utilization of the transportation capacity of the LTL carrier, which in return, reduces the costs. Therefore, LTL carriers can offer competitive shipment rates. Besides the base rate of a carrier in relation to its service quality and business background, the LTL rates are typically determined based on three main factors: origin-destination, shipment size, and freight class (Cerasis, 2016).

- Origin-destination will determine the distance of the shipment to be made, hence will affect the rate of the shipment. While it is expected that the rate would increase with the distance, the shipping rate is not always directly proportional to the distance of the shipment. Some LTL carriers might operate only in specific regions, hence a shipment out of the carrier's region would be subject to higher rates as the carrier might need to use other service providers. Moreover, depending on the carrier's network, the direct distance between the origin and the destination of the shipment will not necessarily define the distance the shipment travels.
- Shipment size is a key factor for an LTL carrier in pricing the shipment. The weight as well as the volume of the shipment are used by LTL carriers to determine the rates. The weight and the volume define the density of the shipment, which is used in determining the freight class. The freight class is then used in calculating the rate for the shipment. Furthermore, LTL carriers offer weight- and/or volume-based discounts to attract larger shipments.
- Freight classification helps describe a shipment's transportability based on its density, handling, stowability, and liability. These factors are all cost sources for a carrier, therefore the freight class will directly impact the rate an LTL carrier charges for a shipment.

Besides these factors, the rate for an LTL shipment will depend on the speed desired, additional services (such as loading/unloading support, residential pickup/delivery, shipments from/to limited-access locations), the carrier's freight minimum and the contract between the shipper and the carrier. Shippers can negotiate rates with carriers based on their shipment frequency and the cumulative amount of different shipments they make with the same carrier. An LTL shipper should understand that what drives a carrier's shipment rates and consider making adjustments accordingly in order to obtain better rates.

What Do the LTL Shippers Want?

As any customer for any service, LTL shippers seek the best service at the best rates from LTL carriers. Of course, just the cost of the service does not reveal the best LTL carrier and the service quality is not straightforward to measure, considering the various aspects of the service that are involved. Essentially, LTL shippers want many things, and thus LTL carrier selection is a multiattribute decision-making problem. We summarize common attributes typically used by LTL shippers for carrier selection in six categories as follows (Lambert et al., 1993; Premeaux, 2009; Williams et al., 2013; Vega et al., 2018). It should be noted that some attributes might be specific to a business type and a business might have other special attributes for evaluating LTL carriers.

- Cost and billing: shippers prefer competitive rates. As discussed earlier, a carrier's shipping rate depends on the origin/destination, shipment size, freight class as well as the speed desired. Furthermore, carriers can offer discounts and a shipper can negotiate rates. In addition, the costs of the other services provided are important for a shipper. Billing accuracy and transparency are also important attributes for LTL shippers. Billing should accurately reflect the shipping charges, how any damages are billed, costs of the additional services, and items included in the charge.
- Time performance: shipping time is a key performance measure of a carrier's service. LTL shippers regard the transit time, transit time reliability, on-time pickups, and on-time deliveries as crucial attributes for evaluating LTL carriers, because these attributes have a significant impact on a shipper's profitability and service quality.
- Shipment restrictions: typically, LTL carriers have restrictions on the shipment sizes and/or the cost of the shipment. These are generally referred to as freight minimums and freight maximums. Freight minimums define the minimum amount required for a carrier to accept a shipment and carriers set freight minimums in order to ensure a certain profit margin from a shipment. Freight maximums define the maximum amount a carrier can accept and carriers set freight maximums considering their fleet and capacity. Freight minimums and maximums should be taken into account by a shipper, as they will significantly affect the cost and transit time of the shipments. In addition, some carriers might have restrictions on what they can ship. For instance, some carriers will not have refrigerated trucks in their fleet, or some carriers will not have the required equipment and/or capability to

ship certain freight classes, such as hazardous materials. Furthermore, some carriers will have restrictions on where they can ship. A shipper should consider such restrictions in selecting a carrier.

- **Service quality:** here, we consider service quality as the set of attributes of a carrier's service other than shipping rates and times. One important service attribute LTL shippers consider is the damages incurred during transit. It is important to define who is liable and how the damages are to be billed. The carrier might offer insurance for the shipment, and LTL shippers should collect data about the damages to their shipments when they use an LTL carrier. Another crucial attribute is information sharing. It is essential for most LTL shippers to have real-time information on their shipment so that they can make necessary adjustments accordingly and/or update the receivers about the status of the shipment. Related to this, a carrier's flexibility and ability to make modifications are also important for an LTL shipper. Things might change, due to the changes in either the carrier's or the shipper's plans, and LTL shippers value the ability to make necessary changes before or during the shipment. Finally, LTL carriers can increase their service quality by offering additional services such as loading/unloading support, packaging services, redelivery and residential pickups and/or deliveries.
- **Customer service:** the level of customer service an LTL carrier provides can be a winning factor. LTL shippers enjoy prompt responses to their inquiries and claims. Furthermore, the relationship between the carrier personnel and the shippers can go a long way in prompting a shipper to work with a carrier. In addition, the professionalism and high working standards of sales personnel, drivers, and executives of a carrier are attractive attributes for LTL shippers.
- **Other attributes:** in addition to the aforementioned attributes, several other factors can attract LTL shippers. Other attributes include but are not limited to security of the shipment, sustainability of the carrier, carrier's brand image and financial stability, use of technology, fleet type and safety, data availability and ease of access to information, and other resources.

Some of the aforementioned attributes are quantifiable, whereas others are more qualitative in their nature. This makes LTL carrier selection a challenging task. LTL shippers can benefit from using third party logistics providers. In addition, transportation management systems and the integration of shipments with existing enterprise resource planning platforms can help LTL shippers manage their shipments better and achieve cost savings, as well as offer higher service levels to their customers. In the following section, we numerically discuss the effect of several key attributes on the logistics costs and service level of an LTL shipper, using an inventory control model.

Inventory Control and the Impact of Key Factors

Inventory control is the key driver of the amount and frequency of the shipments made by a business, and therefore it should be integrated with LTL carrier selection (for a review of transportation mode selection in inventory control models, see [Engbrethsen and Dauzere-Peres, 2019](#)). In this section, a numerical analysis of the impacts of four key LTL carrier attributes on a shipper's expected cost and service level using a continuous review inventory control model is undertaken. Particularly, the well-known (Q, R) model for a stochastic demand inventory control system is applied ([Hadley and Whitin, 1963](#)), where an order of Q units is placed when the on-hand inventory level drops to R . Here, Q defines the shipment size a shipper will be shipping from its supplier. The demand per unit time, here annual demand is used, is a random variable with mean λ and standard deviation ν . The shipper incurs inventory-holding cost (h per unit per year), order-setup cost (K per order), and penalty cost for each unit short (p per unit short). It is assumed that shortages are backordered. Note that shortages can occur only during the delivery of the shipment, that is, lead time, which is considered as the LTL carrier's transit time. Under the settings of the classical (Q, R) model, the shipper's annual expected cost as a function of the order-quantity Q and reorder-point R , denoted by $EC(Q, R)$, is given by:

$$EC(Q, R) = h \left(\frac{Q}{2} + R - \mu \right) + \frac{K\lambda}{Q} + \frac{p\lambda n(R)}{Q}$$

where the first term is the expected annual holding cost, the second term is the expected annual order setup cost, and the last term is the expected annual penalty cost, such that $n(R)$ denotes the expected number of shortages backordered per replenishment cycle and μ denotes the mean of the lead time demand. Assuming a constant purchase cost per unit and a constant unit shipping cost, the annual transportation and procurement costs are omitted from the expected cost function, as these will be constant. One can easily note that as the LTL carrier's unit shipping rate increases, the expected annual cost of the shipper will also increase.

In the following analyses, it is assumed that the annual demand is normally distributed. In addition to analyzing the effects of four key attributes of an LTL carrier on the shipper's expected annual costs, the shipper's service level is also considered. In particular, the changes in the expected portion of the shipper's demand that is not backordered (i.e., the shipper's service level, which is also known as the type-II service level in the (Q, R) model) are also analyzed. The type-II service level represents the shipper's fill rate and is measured as $\beta = 1 - \frac{n(R)}{Q}$. Furthermore, three classes of problem instances are considered based on the coefficient of variance of the shipper's annual demand, denoted by CV , such that $CV = \frac{\nu}{\lambda}$. The three classes of problem instances are defined such that $CV \in [0, 1, 0.4]$, that is, low variability, $CV \in [0.4, 0.7]$, that is, medium variability and $CV \in [0.7, 1]$, that is, high variability of the shipper's annual demand. For each problem class, 100 problem instances are randomly generated as follows. First, the cost parameters are randomly generated from uniform distributions such that $h \in [1, 10]$, $p \in [1, 10]$, and $K \in [150, 250]$. After that, λ is randomly generated such that $\lambda \in [2, 000, 10, 000]$ and CV is randomly generated depending on the problem class.

Figure 1 The impact of transit time on shipper's costs and fill rate.

Once λ and CV are known, ν is also known. Each problem instance from a problem class is solved with the same 10 varying values of the key LTL carrier attributes under investigation and the average results over 100 problem instances for each problem class are summarized.

Impact of Transit Time

As it is discussed earlier, the transit time of an LTL carrier for a shipment is one of the key attributes for the shipper. The transit time defines the lead time for the shipper, which directly influences the shipper's annual expected cost and fill rate. Here, the transit time is considered to be deterministic, and τ denotes the corresponding lead time. Fig. 1 summarizes the changes in $EC(Q, R)$ and β under the shipper's optimal (Q, R) policy as τ increases for different problem classes, respectively.

It can be observed from Fig. 1 that the expected annual cost increases, whereas the fill rate decreases, as the lead time increases. These are expected results because the longer the transit time is, the higher a shipper's shortage probability becomes, which, in turn, imply increased costs and decreased service levels. Furthermore, one can notice that when the variability of a shipper's annual demand is larger, that is, when CV is larger, the adverse effects of increased lead time duration are relatively more severe.

Impact of Transit Time Variability

The lead time variability measures the transit time reliability of the LTL carrier. In order to analyze the impact of lead time variability, we randomly generate mean lead time for a problem instance, and then solve the same problem instance with 10 different lead time standard deviation, w , values. Note that one can characterize the lead time demand distribution easily given the mean and the standard deviation of the lead time along with the details of the annual demand. Fig. 2 summarizes the changes in $EC(Q, R)$ and β under the shipper's optimal (Q, R) policy as lead time variability w increases for different problem classes.

Fig. 2 reveals that, as the lead time variability increases, the expected annual cost increases and the fill rate decreases. These are expected results because increasing lead time variability implies a higher probability of shortages which, in turn, implies higher penalty costs. To avoid these, the shipper might increase inventory levels which increases inventory holding costs. Furthermore, one can notice that when the variability of a shipper's annual demand is larger, that is, when CV is larger, the adverse effects of increased lead time variability are relatively less severe because, with larger CV, the shipper's demand during the lead time already has high variability, thus increasing the lead time variability adds up relatively less than it adds up for the cases with smaller CV values.

Figure 2 The impact of transit time variability on shipper's costs and fill rate.

Figure 3 The impact of freight minimum on shipper's costs and fill rate.

Figure 4 The impact of freight maximum on shipper's costs and fill rate.

Impacts of Freight Minimums and Maximums

To analyze the effects of an LTL carrier's freight minimums and maximums on a shipper's expected costs and service levels, the following definitions are applied. Given a problem instance, let Q^* be the shipper's optimal shipment size without any restriction on the shipment size, that is, $(Q^*, R^*) = \operatorname{argmin}\{EC(Q, R)\}$. To define binding freight minimums, the following problem instance is solved subject to $Q \geq \delta Q^*$, where δ increases from 1 to 1.5 in increments of 0.1, and let $(Q^-, R^-) = \operatorname{argmin}\{EC(Q, R) : Q \geq \delta Q^*\}$. Similarly, to define binding freight maximums, the following problem instance is solved subject to $Q \leq \delta Q^*$, where δ increases from 0.5 to 1 in increments of 0.1, and let $(Q^+, R^+) = \operatorname{argmin}\{EC(Q, R) : Q \leq \delta Q^*\}$. In order to determine (Q^-, R^-) and (Q^+, R^+) for a problem instance, the interior-point method is used. Furthermore, in this analysis, it is assumed that the carrier's transit time is deterministic and that lead time is randomly generated for each problem instance.

Fig. 3 illustrates the changes in the shipper's annual expected costs and service levels as the freight minimum increases from Q^* to $1.5Q^*$ for different problem classes. Similarly, Fig. 4 illustrates the changes in the shipper's annual expected costs and service levels as the freight maximum increases from $0.5Q^*$ to Q^* for different problem classes.

It can be observed from Figs. 3 and 4 that an LTL carrier's freight minimums and maximums hinder the shipper's efficiency and diminish the service quality. Indeed, freight minimums and maximums mean less flexibility for a shipper, hence if the shipper has to use the LTL carrier and obey the carrier's freight minimum and maximum, the shipper might need to deviate from its optimal operational plans which, in turn, reduces the shipper's efficiency and service quality. Finally, it can be noticed that the effects of freight minimums and maximums are similar for different characteristics of the shipper's annual demand (i.e., different problem classes).

Conclusion

This chapter has discussed the basics of carrier selection for LTL shipments. In particular, LTL carrier selection is crucial for the success of a business and LTL carrier selection affects the performance of strategic, tactical, and operational planning decisions in a supply chain. A shipper should pay attention to the working principles of LTL carriers and understand what drives LTL shipment rates, in order to effectively manage its LTL shipments. Nonetheless, shipping rates should not be the sole focus in selecting an LTL carrier. Typically, shippers regard multiple attributes simultaneously while evaluating potential LTL carriers. These attributes are related to the costs and billing, transit time, shipment restrictions, service quality, customer service, and other aspects of the services offered by LTL carriers. Of course, the importance of each specific attribute will depend on the shipper; therefore, the shipper should also understand the consequences of its LTL shipment decisions on the overall operations of its business.

While some of the LTL carrier attributes can be quantified, some of them are less tangible. Through numerical analyses using an inventory control model, the effects of several key LTL carrier attributes on a shipper's expected costs and service level have been demonstrated. Such inventory control models should be integrated with LTL carrier selection for cost efficiency and improved service levels. Furthermore, it is worth noting that there exist various multicriteria decision-making tools, such as the analytic hierarchy process, technique for order preference by similarity to ideal solution, and multiobjective optimization, that can be used for selecting LTL carriers. LTL shippers should carefully use such tools and try to include as much detail as possible in selecting carriers for their LTL shipments.

Decarbonization Framework

Frameworks for analyzing the relationships between the economy and road freight transport have been developed since the mid-1990s, and the frameworks have been expanded since to include the environmental effects and also monetary valuation of the environmental effects for determining the external costs of logistics operations. The basic structure of the frameworks has remained similar and included the components of economic development, freight transport performance, and environmental outputs. A detailed framework for illustrating the complexity of decarbonizing road freight transport is used in this article, as shown in Fig. 1.

Framework Indicators

The decarbonization framework disaggregates the link between the economy and the CO₂ emissions of road freight transport into eight indicators. The first indicator is Gross domestic product (GDP) or added value, usually presented using fixed prices to enable time series analysis. GDP is a widely used indicator for national economic output, and it has usually been categorized in the decarbonization framework as an aggregate or output value, but it is actually a variable, which needs to be forecast, unlike the aggregates of the framework, which are calculated as the results of forecast indicator values.

The value density is defined as the ratio of GDP to the total weight of goods transported within a country by all modes of transport. The value density is expressed as the unit €/t. Value density can also be defined as the ratio of GDP to the total weight of goods produced, but many countries lack the data of the weight of goods produced. If such data are available, an indicator called the handling factor, that is, the ratio weight of goods transported and produced, can be used.

The modal split is defined as the percentage of total weight of goods transported by road and other modes. The energy efficiency and CO₂ emissions of other modes than road freight can be studied using a similar framework as in figure for each mode. However, the focus of decarbonizing freight transport is usually on road freight transport because it is the most important mode of freight transport in most countries.

Average length of laden trips expresses the average distance, which trucks travel on one trip. It is calculated by dividing the mileage of laden trips by the number of laden trips. Average length can also be calculated by dividing the road haulage (tkm) with weight of goods transported by road, but this method is slightly misleading, as the payload and type of trip (long haul or pick up/distribution round) affect the road haulage.

The fifth indicator in the decarbonization framework is the average load on laden trips, which is expressed in tons. It is calculated by dividing the weight of goods transported by road with the number of laden trips. This actually gives the value for the average maximum load on laden trips, that is, the changes in the load during a pick up/distribution trip is not taken into account. Changes in the load during a trip can be taken into account if the average load is calculated by dividing the road haulage by the mileage of laden trips. The average load on laden trips can be disaggregated into vehicle utilization rate, or 'load factor', and the average maximum capacity of trucks. The vehicle utilization rate is the ratio of actual load to maximum load.

Figure 1 Road freight decarbonization framework.

Empty running is the percentage of total mileage run without a load. It is a characteristic feature of road freight transport as goods almost never return loaded to the point of origin. Average load and empty running are sometimes analyzed together as a single vehicle utilization indicator. One such indicator, is the “efficiency of vehicle usage” indicator, which is calculated by dividing ton-kilometers (tkm) by mass-kilometers, with mass meaning the sum of the vehicle’s own weight and the payload (Léonardi and Baumgartner, 2004). However, some valuable information may be lost by doing this, because even though empty running and average loading are interrelated, they are also determined by separate affecting factors.

Average fuel consumption is the amount of fuel needed for the trucks to travel a certain distance. The unit l/100 km is often used, but fuel economy can also be expressed using the inverse ratio of miles per gallon (mpg). Average fuel consumption is the result of a very complex system of, for example, engine, vehicle design, driving behavior, vehicle loading, and traffic conditions. There are usually no direct data available in road freight statistics on the fuel consumption, so it has to be estimated separately.

The last indicator in the decarbonization framework is the fuel CO₂ content, which expresses how much carbon dioxide is emitted when burning 1 L of fuel. In many countries, the fuel used in trucks is virtually solely diesel. Diesel has a fixed CO₂ content of approximately 2.66 kg/L. Biodiesel or some other alternative fuels may replace some or all of diesel and change the CO₂ content.

Framework Key Indicators

In addition to the eight indicators, three key indicators are defined. These key indicators enable analysis of the issue at a more aggregate level and can be used especially in decoupling analysis. On the most aggregate level, CO₂ intensity can be analyzed to find out whether decarbonization, that is, the decoupling of road freight transport CO₂ emissions from economic growth, has occurred. CO₂ intensity is the ratio of road freight CO₂ emissions to GDP (g/€), so decreasing CO₂ intensity means decarbonization has occurred. However, usually some additional information about the reasons for decarbonization is wanted and the simplest way of

doing this is by introducing the key indicators of transport intensity and energy (or CO₂) efficiency. Until recently, the changes of energy and CO₂ efficiency were the same, due to the fixed CO₂ content of diesel, but alternative energy is increasingly used and needs to be taken into account in the future.

Transport intensity is the ratio between road haulage (tkm) and economic output (GDP). It expresses the changes in the demand for road freight transport in the economy. The term immaterialization can be used of a situation, where decoupling of road haulage from economic growth occurs. Energy efficiency expresses the changes in the efficiency of the supply of road freight transport. Also the term dematerialization can be used to describe the decoupling of transport CO₂ emissions (or energy consumption) from road haulage. Energy efficiency is defined as a ratio between an output of performance, service, goods, or energy and an input of energy. The energy efficiency of road freight transport is thus generally the ratio between road haulage and energy consumption, indicated as ton-kilometers per kilowatt-hours. This can also be turned the other way around to yield energy intensity (kWh/tkm). Other possibilities for indicating the same subject include energy intensity (MJ/tkm), fuel efficiency (koe/tkm, where koe means kilograms of oil equivalent) and emissions efficiency (g CO₂/tkm), as well as CO₂ efficiency (tkm/kg CO₂). All these indicators are interdependent as the current major fuel of road freight vehicles, diesel, has fixed energy content (approximately 10 kWh/L, 36 MJ/L, or 0.87 koe/L) and produces a fixed amount of CO₂ (2.66 kg/L) when burned in the engine.

Limitations of the Decarbonization Framework

The decarbonizing framework disaggregates the relationship between the economy and CO₂ emissions into indicators, which can be analyzed to find out the causes of changes. However, by doing that, some complexity may be lost and one should be cautious not to lose sight of the various feedback loops between the indicators. For example, the value density affects the modal split, as high value goods are more often transported by road or air, and the average load on laden trips and share of empty running affects the average fuel consumption. While the framework includes the modal split, other modes of transport than road freight are omitted from the framework, but similar analysis can be made of other modes and changes in indicators in other modes can affect road freight. The geographical scope of the study is also an important issue. It can be seen from the various studies that analyses have mostly been made at a national level, as the data are best available for that scope. There are limited and scattered data available for freight analysis because of a variety of units for measuring freight movements, confidentiality issues, various decision makers involved in a shipment and different types of loads. The solution is to combine both quantitative and qualitative data from several sources.

The framework has mainly been utilized for studying the changes that have affected the road freight transport sector. It has also been used somewhat, and increasingly, for forecasting the future development of road freight transport and its environmental effects, mainly CO₂ emissions. Forecasts of the CO₂ emissions of road freight transport should be produced by combining various forecasting methods, such as focus group discussions, Delphi survey, scenarios, and spreadsheet modeling, with the framework. This is because the accuracy of forecasts that rely on trend extrapolation or linking freight transport with economic development is considered low. Extrapolation is useful only in stable conditions with continuous trends, but road freight transport has changed over the past decades and is likely to change in the future due to, for example, globalization and climate change mitigation. Hence, the elasticity of freight transport to GDP changes over time in relation to the maturity of commercial exchange between countries. This has to be taken into account when building long-term business-as-usual scenarios, but on short-term scenarios elasticity might have only a minor effect.

Affecting the Determinants of Road Freight Transport

There is a wide variety of measures for decarbonizing road freight transport, because each indicator of the decarbonization framework is affected by various determinants, which in turn may be affected in various ways to change the indicator toward a more sustainable direction.

Gross Domestic Product

The necessity of economic growth (as measured by GDP) has been the dominant paradigm in politics since the Second World War. GDP is widely identified with social welfare and hence the need for growth is taken for granted. However, there is a growing critique toward GDP for being inadequate in capturing human welfare and the environmental and social problems, which accrue from continuous growth. Several alternatives for GDP have been developed, including, for example, the index of sustainable economic welfare, sustainable national income, genuine savings, and the human development index. Economic and social concerns have led to the emerging idea of degrowth, which is defined as an equitable downscaling of production and consumption that increases human well-being and enhances ecological conditions at the local and global level, in the short and long term.

The downscaling of production and consumption of goods results in decreasing GDP and would decrease the demand for road freight transport. However, it seems highly unlikely that any national government would take downscaling of production and consumption as a policy measure for decarbonizing road freight transport.

Value Density

Decarbonizing road freight transport by increasing the value density is politically much more acceptable than by decreasing GDP. When value density is considered, it is essential to distinguish between changes at a national and a global scale. At both the national and global scale, decarbonization through increasing value density may occur if:

- lighter materials are used to produce same goods,
- smaller goods are produced to fulfill the same purpose,
- goods are substituted with services, and
- the effect of these changes is greater than the growth of consumption (GDP).

Offshoring of manufacturing to other countries while maintaining the headquarters of the company in another decreases the weight of goods produced and transported in the country of headquarters, but maintains the level of GDP generated in that country and maintains the weight of goods produced at a global scale. The effect of offshoring on the global total haulage (tkm) is yet another matter, as it depends on the locations of raw materials, production and final consumption, and thus the handling factor (ratio of weight of goods transported and produced) and the average length of trips. The handling factor can be reduced through:

- disintermediation, that is, eliminating links in supply chains;
- vertical integration, that is, locating interrelated processes on the same site; and
- decreasing intermodality, that is, eliminating road feeder movements by connecting or relocating the site to railroad, port, or airport.

Modal Split

Modal split affects the energy efficiency and CO₂ emissions of road transport, as it defines what kinds of goods are transported in each transport mode. Waterway and rail transport are generally considered to be more energy efficient than road transport, but this view is also questioned. The energy efficiency is highly dependent on the utilization of payload capacity in each mode. With average loading, rail transport has the lowest CO₂ emissions per ton-kilometers, closely followed by coastal shipping and inland waterways, whereas trucks have considerably higher emissions and vans far higher still (Fig. 2).

No mode of freight transport can be categorically designated as the most environmentally friendly. The potential for decarbonization through modal shift depends on:

- energy efficiency of the mode,
- carbon intensity of the energy source by mode,
- utilization of equipment, and
- energy use of modal interchange.

This has to be taken into account when the energy efficiency and CO₂ emissions of different modes are evaluated. It is desirable from the decarbonization perspective to promote co-modality, the efficient use of transport modes on their own and in combination. If sufficient decarbonization potential is available, modal shift can be promoted through infrastructure investments and direct support for rail and waterways equipment purchase and operations.

Figure 2 Energy efficiency of various freight transport modes. Source: Based on VTT (2019).

Average Length of Laden Trips

The average length of laden trips is mainly affected by the geographical scale of sourcing and market areas of production, as well as the location of production sites. The globalization of sourcing and markets, with centralization of production and warehousing, has been the major trend in the global economy in recent years. These changes may decrease or increase the average length of haul at a national scale, and it is very difficult to influence these changes. Furthermore, the changes in average length of haul influence the modal split, vehicle loading, and the level of empty running, so it is very difficult to implement decarbonizing policy measures directed at the average length of laden trips. At haulier level, decreasing the average length of laden trips is possible by improving the vehicle routing and scheduling, possibly with the help of optimization software (computerized vehicle routing and scheduling). Also relocating distribution centers, using a hub and spoke network, and participating in open cooperation networks are possible decarbonization measures, which also affect the vehicle loading and empty running.

Average Load on Laden Trips

Increasing the average load on laden trips increases the fuel consumption on the basis of l/100 km, but decreases the mileage required to perform the same haulage (tkm), and thus improves the energy efficiency (tkm/kWh) and decreases the total CO₂ emissions. Average load is mostly considered in terms of weight, although in many cases the area or volume of the cargo space is the limiting factor, rather than maximum weight. However, data on volumetric vehicle fill are rarely available at a sufficient level of detail for analysis. Average load may be disaggregated further into maximum payload weight and vehicle utilization rate. This disaggregation may be helpful, as the largest trucks are not suitable for every operation (e.g., in urban areas) and, hence, the changes in the average load may be caused by necessary changes in average maximum payload weight of the fleet.

Opportunities for decarbonizing road freight transport through increasing average load on laden trips are numerous, but mainly constrained by the interfunctional relationships between transport and other business activities. Increasing the transport cost through fuel taxation or road user charging may be used as policy measures to increase the importance of vehicle utilization. Other policy measures include allowing larger trucks and relaxing access restrictions, as well as promoting better vehicle loading through awareness campaigns and benchmarking information.

Policy measures can only guide companies to improve their vehicle utilization, but better results are gained if companies realize the potential cost savings and implement measures such as:

- nominated day delivery system, which decreases the inefficiency caused by demand fluctuations;
- more space efficient cargo handling equipment and packaging, which reduce the need for packaging without compromising the protection of goods from damage;
- double deck trailers, which allow stacking pallets or roll cages to better utilize the maximum payload weight;
- intra- and intercompany cooperation, which decreases the inefficiency caused by geographical imbalance of goods flows and lack of interfunctional coordination; and
- lightweight vehicles, which decrease the own weight of the vehicle and increase the maximum payload weight for transporting more high-density goods.

Empty Running

Most reasons for inefficiency and decarbonization measures mentioned for the average load on laden trips also apply for empty running, but empty running is even more dependent on the level of intercompany cooperation. The potential for increasing backloading and reducing empty running is not fully utilized, quite simply because there is a lack of knowledge of available loads. Even if there is such knowledge, backloading may not be realized because outbound delivery is prioritized and there is an increased risk for delays with backloading. Also, the vehicles or cargo handling equipment may not be suitable for the backloading products, or the driver's working hours limit the possibilities for backloading.

Intercompany cooperation, through outsourcing of freight operations to a logistics service provider or through establishing a network of hauliers, improves the sharing of knowledge on backloads. Also the wider use of web-based tendering of freight transport services improves the level of knowledge. Increased visibility of freight operations and cooperative efforts for avoiding delays can be used to develop confidence between the shipper and haulier and, thus, make backloading more acceptable. Empty running also decreases when reverse logistics, such as the recycling of packaging waste, reuse of handling equipment, or refurbishment of products, increases. Transport policy may affect empty running by increasing the cost of transport, relaxing the working time and cargo handling restrictions, as well as by standardizing cargo-handling equipment.

Average Fuel Consumption

In addition to the vehicle loading, the fuel consumption is determined by three main factors: traffic conditions, vehicle specifications, and driver behavior. Traffic conditions include road geometry and traffic flow. Road geometry affects fuel consumption mostly in hilly terrain, but winding roads may cause braking and acceleration, which increases fuel consumption. Traffic flow is affected by the number and behavior of other road users and by the regulation of traffic flow, that is, traffic lights, speed limits, etc. The effects of

Table 1 Fuel saving measures and approximate potential savings

Aerodynamics	Under-run air dam	<1%
	Cab roof fairing	4%
	Cab side edge turning vanes	<1%
	Body/trailer side panels	1%
	Body/trailer front fairing	3%
	Tipper sheeting systems	<1%
	Teardrop trailer	10%
	Sloped roof trailer	5%
	Reduce height of vehicle	3%
	Louvered spray suppression flaps	3%

road geometry are minor compared to the effects of irregular traffic flow. Hence transport policy may decarbonize road freight transport by investing in road infrastructure, improving road traffic management, introducing road user charges, and relaxing restrictions for night deliveries. Hauliers, on the other hand, may use dynamic vehicle routing to avoid congested roads and negotiate with their customers to reschedule the deliveries.

Vehicle specifications affect the fuel consumption in numerous ways. First, there are significant differences in the fuel consumption between the new trucks of different brands. There are several possibilities for improvements in truck engine and transmission, such as, downsizing, supercharging, and automated manual transmission, which when combined result in substantial fuel savings. The improvement with greatest fuel saving potential is the hybrid electric powertrain. Truck manufacturers are responsible for the development of truck powertrains, but the hauliers may decarbonize their operations by purchasing trucks with low consumption and the government can help hauliers to make the right decision by introducing fuel consumption standards. In addition to engine and transmission, there is a variety of measures which the haulier can implement to achieve considerable fuel savings. **Table 1** summarizes some of these measures and their approximate potential fuel savings.

Driving behavior has a great effect on fuel consumption. The difference between drivers can be up to 30%. Because of this, many companies have implemented ecodriving training and gained short-term fuel savings. However, the effects of ecodriving training often decrease in the long term if the driving behavior is not monitored and feedback is not given. Regular monitoring can also include an incentive system for drivers. However, there are challenges facing incentive systems that are operated within transportation companies, such as the complexity of implementation, lack of accurate consumption data, and lack of information on how to operate such a system. Monitoring driver performance fairly is a complex matter, because weather, traffic, road geometry, vehicle and load carried are all constantly changing, independent of a driver's actions. However, each can have a considerable effect on fuel consumption. Nevertheless, current onboard computers enable taking these issues into account to establish a fair incentive system. Policy makers can promote ecodriving through awareness campaigns, mandatory ecodriving as part of driving license training and fiscal incentives for the purchase of onboard monitoring equipment.

Fuel CO₂ Content

The final indicator in the framework is the carbon dioxide content of fuel. Road freight transport may be decarbonized by using alternative fuels such as renewable diesel, natural gas, or electricity. Electric vehicles depend on batteries, which are heavy and also quite large, but still have very limited range. These characteristics make them unsuitable for transporting heavy goods over long distances, but possible to exploit in urban distribution operations and the long haul of light goods. However, the decarbonizing effect of electric vehicles depends on the source of electricity.

Natural or biogas vehicles have a greater range than electric vehicles, but require large investments in distribution infrastructure. Natural gas has about the same CO₂ content as diesel and thus does not have a decarbonizing effect. Biogas, on the other hand, reduces methane, which would otherwise be emitted from the waste disposal process and thus reduces greenhouse gases, but the production of biogas is still very limited.

Renewable diesel is currently the most viable option for decarbonizing road freight transport through decreasing the CO₂ content of fuel. Renewable diesel may be produced from various sources, including vegetable oil, frying oil and animal fat, and the CO₂ reduction depends on the source. The well-to-wheel GHG emissions savings from renewable diesel are typically 30%–90%

compared to fossil diesel. However, the savings may be much smaller when the changes in land use are taken into account. Nevertheless, renewable diesel has advantages as an alternative to diesel. First, it is partly or completely compatible with the current diesel engines, and it uses the same distribution infrastructure. Second, it can be produced from waste or cellulosic crops, so it does not compete with food production or require land use change. Because of these issues, renewable diesel is already widely used blended with fossil diesel and its use is likely to increase. The political pressure for increasing the use of renewable diesel is certainly great due to its benefits in decreasing oil dependency and increasing the number of sources of energy and domestic self-sufficiency in energy.

Brief Historical Background

The rebound effect as a phenomenon was first presented by the English economist William Stanley Jevons in his book “The Coal Question” in 1865. He observed that technological improvements resulted in more efficient utilization of coal, but this also led to an increase in the consumption of this fuel in several industries during the 18th and 19th centuries (Jevons, 1865). This unforeseen effect, initially known as the “Jevons Paradox,” was revisited in the 1980s by both J. Daniel Khazzoom and Leonard G. Brookes, who discussed the issue independently. They stressed that, at a macroeconomic level and contrary to what common sense suggests, energy efficiency gains (or in the words of Leonard G. Brookes, “reductions in energy intensity of output”) that are not harmful to the economy, are linked with increases in energy consumption (Khazzoom, 1980; Brookes, 1990).

The validity of the Khazzoom-Brookes hypothesis was fiercely debated in a series of academic articles in the 1990s (Brookes, 1990,1992; Grubb, 1990,1992). In 1992, Harry D. Saunders demonstrated that under certain assumptions the postulate is consistent with results directly obtained from neoclassical growth theory. He identified two channels through which the rebound effect may arise (Saunders, 1992). First, energy efficiency improvements result in energy appearing cheaper than other inputs, which implies that energy will substitute other input factors such as labor. Second, increases in economic growth lead to an additional boost in energy consumption. Since then, despite these theoretical underpinnings, the scale and relevance of the rebound effect have remained contentious and spurred by the development of an extensive empirical literature.

What is the Rebound Effect?

From a theoretical point of view, the rebound effect describes the potential energy savings that are offset when there are energy efficiency enhancements. In other words, rebound effects imply that energy efficiency improvements may lead to less than proportional reductions in energy consumption. In a general and simplified way, an energy efficiency improvement can be viewed as a reduction in energy use while the demand for energy services is maintained and the comfort and the quality of life are not diminished. Full potential energy savings are usually mechanically derived by assuming that the demand for energy services remains unchanged after energy efficiency gains. However, energy efficiency enhancements implicitly imply a reduction in the marginal cost of providing a given level of energy services, which may lead to an increase in demand for those services and consequently to an increase in energy consumption. It is possible that this reaction may partially or fully offset the initial expected energy savings, often described as the rebound effect or take-back. If the magnitude of the rebound effect is non-negligible and the phenomenon is overlooked, the benefits from energy savings may be overstated and policies aimed at reducing energy consumption through promotion of energy efficiency may not be fully effective. This in turn may lead to decisions such as the (over) allocation of public funds to ineffective environmental and energy policies.

From consumer choice theory in microeconomics, the rebound effect can be understood as a combination of income and substitution effects (Gillingham et al., 2016). The substitution effect refers to a situation in which part of the demand for one good or service is replaced by the demand for another good or service simply due to a change in their relative prices. The income effect also implies a change in the consumption pattern of goods and services, but it arises from the increase in consumer purchasing power due to the price reduction. The literature on the rebound effect has often attempted to pin down the definition and implications of the effect through distinguishing at least three types of them, namely, direct, indirect, and economy-wide rebound effects (Sorrell and Dimitropoulos, 2008).

The most apparent effect is the so-called direct rebound effect. This type of rebound implies that an improvement in energy efficiency for a particular energy service decreases the effective price of that service and provides incentives to increase the demand for the service. Therefore, the reactions of individuals tend to offset the expected energy savings that could be attributed to energy efficiency improvement. The indirect rebound effect arises from energy savings due to energy efficiency enhancement when they are reverted into demand for other goods and services that require energy for their provision. The economy-wide rebound effect relates to the reduction in the price of intermediate and final goods in the economy due to the decrease in real price of energy services. This results in adjustment of the prices and quantities of goods and services consumed in the economy. These adjustments create a bias toward consumption of the goods in the most energy intensive sectors, which may then yield an increase in overall energy consumption.

The rebound effect is generally measured as the percentage of the potential energy savings that are not achieved. They normally take values between 0% (zero rebound effect) and 100% (full rebound effect). However, rebound effects can also take values larger than 100%, labeled as “backfire” in the literature (Saunders, 1992), which means that improvements in energy efficiency can lead to a higher level of energy consumption than before the efficiency improvement. The opposite case, that is, a negative rebound effect, which can seem counterintuitive, is labeled as super-conservation (Saunders, 2008). This rebound effect represents a reduction in energy consumption that exceeds the initial expected savings. The diverse definitions, set of methodologies applied, data, sectors and countries analyzed, and the resulting broad range of results obtained in the empirical literature have helped to keep the debate about the rebound effect open.

It is worth noting that some researchers consider the rebound effect as a natural adjustment to changing economic factors. In essence, this means that the rebound effect can be considered as a reoptimization process in response to price and income variations (Borenstein, 2015). From that perspective and using standard economic analysis, the rebound effect can be seen as a welfare improvement. However, it should be noted that in order to assess the net impact of the rebound effect on overall economic welfare, the external costs generated by this phenomenon (e.g., through GHG emissions) should also be incorporated in the analysis.

The Rebound Effect in Road Freight Transport

The literature on the rebound effect has focused both on the analytical definitions of the concept and its empirical measurement using alternative approaches generally based on elasticities. Elasticities are measures, often used in economics, to represent the proportional change of a specific variable in relation to the change of another variable. A basic description of the rebound effect can be proposed by using the elasticity of the demand for energy services with respect to energy efficiency. This elasticity represents how demand for energy services change (and hence, also the energy demand) when there is an increase in energy efficiency. The estimation of this type of elasticity is contentious because data on either energy services and energy efficiency are often unavailable or flawed in terms of accuracy. In road freight transport, measures such as vehicle or ton kilometers are frequently used for energy services. However, independent estimates of fuel efficiency are normally difficult to use due to lack of information or insufficient variation within the data.

Instead, own-price elasticities of the demand for energy have frequently been econometrically estimated and used as indirect measures or proxies for the rebound effect. A great majority of studies assume that the response to changes in energy price is equal to the response in changes to energy efficiency. However, it has been shown that, especially in the case of transport, this approach is likely to overestimate the rebound effect due to the endogeneity between energy prices and efficiency choice (e.g., through increasing load factor or purchasing more efficient vehicles), since these two factors are not independent from each other. Therefore, price-induced energy efficiency improvements should not be neglected when analyzing rebound effects to avoid biased estimates. Other likely sources of bias, when rebound effects are econometrically estimated, are the overlooking of trade-offs between energy and time costs, the analysis of rising energy price periods only (which are generally linked with high energy price elasticities) and the correlation between changes in energy efficiency and changes in input costs such as capital costs (Sorrell and Dimitropoulos, 2008).

The empirical research on the rebound effect in the transport sector has yielded a broad range of results both for the short and the long run. However, most of these results have been estimated to be between 10% and 30% (Sorrell, 2007; Hymel et al., 2010). The wide range of results has been a consequence of the differences in the definitions of the rebound effect, the type of elasticities and the approaches used, the countries analyzed and the level of aggregation in the data used. Nonetheless, as it has been remarked by some authors, there is still little research on the rebound effect in road freight, despite the need to assess the effectiveness of the policies adopted to reduce fuel consumption in the sector.

Recent surveys show that, on average, rebound effects in road freight transport are estimated to be between approximately 0% and 40% in the short run, while in the long run the values range between 10% and 85%. This is not unexpected in economic analysis. Elasticities are often higher in the long run than in the short run because changes and adjustments, especially in the stock of capital, are more likely to

happen over longer periods of time. However, these results reveal again that even when we restrict the rebound effect analysis to road freight transport, there is still an ample range of results arising from the diverse data, countries, and approaches used.

For instance, the use of a theoretical framework taken from thermodynamics and evolution, in conjunction with a traditional economic approach, has been proposed to explain the rebound effect (Ruzzenenti and Basosi, 2008). This methodology has identified an increase in the energy efficiency of road freight transport in Europe of 40% between the second half of the 1970s to the first half of the 1990s. The main argument is that, in more complex systems, there is a greater offset of the positive effect from higher energy efficiencies. Network theory has also been proposed to study the direct rebound effect in the European road freight transport sector (Ruzzenenti and Basosi, 2017). This approach provided negative rebound effects, that is, “superconservation,” indicating that energy efficiency improvements, along with energy prices, proved to be successful in reducing energy consumption in Europe in context of increasing demand for freight transport services.

European road freight transport has been analyzed using a stochastic frontier analysis approach taken from the efficiency and productivity analysis literature (Llorca and Jamasb, 2017). The results indicate that the achieved energy efficiencies are retained to a large extent. The average rebound effect is found to be 4%, but with large differences across the EU countries. Moreover, the rebound effect is found to be larger in countries with a higher share of trucks with respect to the total number of vehicles in the sector, as well as a better quality of transport infrastructure. In addition, the existence of a strong railway freight transport sector seems to be linked with a lower rebound effect. It is also shown that significant costs associated with environmental externalities can arise, even in countries with a small rebound effect, due to the large scale of their road freight transport activity.

Computable general equilibrium models have been frequently utilized in the literature to obtain economy-wide measures of the rebound effect. For instance, this approach has been used to analyze the oil rebound effect from energy efficiency improvements in the Scottish commercial transport industry (Anson and Turner, 2009). A rebound effect of 36.4% was found in the short run and 39.2% in the long run for the sector. At economy-wide level, the rebound effect was found to be 36.5% in the short run and 38.3% in the long run. The study also found a disinvestment effect, which implies that in most cases the long-run effect is constrained by a disinvestment that reduces the productive capacity in the energy sectors.

The case of demand for road freight transport in Portugal has been analyzed using a two-stage least squares model (Matos and Silva, 2011). Using aggregate time series data for the period 1987–2006, the study considers the changes in the energy cost of transport, while correcting for the endogeneity of the price variable. It shows that a large share of the operating costs in the road freight industry depends on energy consumption, and an increase in fuel efficiency that reduces these costs will in turn result in a significant increase in demand for energy services. The rebound effect is estimated to be approximately 24%.

The fuel used in the trucking industry of Denmark has been studied using aggregate time series data (De Borger and Mulalic, 2012). Using a simultaneous equations model, a rebound effect of 10% in the short run and 17% in the long run was found for the period 1980–2007. Moreover, the study found that higher fuel prices increased the average capacity of trucks. This feature also led the firms to invest in new and more efficient trucks. The joint influence of their findings suggests that the effect of an increase in fuel prices on fuel use is not very relevant. The results show the short-run and long-run price elasticities to be -0.13 and -0.22 , respectively. They also find a reduction in the realized energy efficiency of the trucking industry in Denmark. The study justifies this reduction as being partially due to rising congestion and “Just-in-Time” behavior of firms, which is also a consequence of the reduction in the utilization of vehicle capacity.

In the case of the United States, some recent studies estimate fuel price elasticities for single-unit truck operations and the combination trucking sector in the country (Winebrake et al., 2015a; 2015b). These analyses apply first-difference and error correction models to time series data for the periods 1980–2012 and 1970–2012, respectively. The authors state that their estimates may, under certain assumptions, be used as a proxy for the rebound effect. They find fuel price elasticities that are not statistically different from zero, although in the case of the combination trucking sector this has occurred since the deregulation of the sector in 1980. They offer possible explanations for their findings, such as the lack of incentives for firms to reduce travel or fuel consumption, adjustments in other modifiable operational costs, the “principal-agent” problem or the nature of freight transportation. However, another study of the United States using detailed truck-level microdata from over 100,000 medium- and heavy-duty vehicles estimated a rebound effect of 30% for tractor trailers and 10% for vocational vehicles (Leard et al., 2016). This study suggests that US regulatory agencies (EPA and NHTSA) might have overestimated long-term fuel and GHG savings from their cost benefit analysis of the truck standards applied.

The case of China has been studied using a double logarithmic regression equation and an error correction model to analyze the direct rebound effect in the short run and long run of different regions of the country from 1999 to 2011 (Wang and Lu, 2014). It found a partial rebound effect in the long run between 52% and 84% for different provinces of China. This implies that a large share of the expected reduction in energy demand could not be achieved and the policies intended to improve energy efficiency are not effective. Nevertheless, they find evidence of a slight super conservation effect in the short run.

The long-run direct rebound effect in the UK road freight transport has been analyzed using time series data for the period 1970–2014 (Sorrell and Stapleton, 2018). The analysis uses different model specifications, conducting several tests to check the robustness of the specifications and using diverse elasticities. It found a direct rebound effect of 61%. Using the most robust models, the direct rebound effect was 49%, while the individual estimates ranged between 21% and 137%. The study points to three possible explanations for these results. First, the large sensitivity of the operators to fuel cost, because it represents one-third of total operational costs. Second, the small variation of fuel efficiency and the fuel costs of the goods moved in the country could be causing unreliable results. Third, the increases in vehicle weight limits, which have encouraged more activity in the sector.

Policy Aspects

In recent decades, there has been an increasing interest in the adoption of energy and environmental policies that attempt to stimulate the reduction of energy consumption. The main goals of these policies are to minimize the dependence on fossil fuels and mitigate local air pollution and GHG emissions. This has been particularly relevant for energy-intensive sectors such as transportation. In 2010, freight transport was estimated to account for about 43% of global energy use in transport, which in turn represented 12% of total energy consumption and 10% of energy-related CO₂ emissions (IPCC, 2014). Moreover, in forthcoming years, the amount of fuel used by the trucking industry is expected to rise in the United States and the EU (Léonardi and Baumgartner, 2004; IEA, 2010; De Borger and Mulalic, 2012), where trucks and vans emit 67% of the GHG emissions associated with transport (McKinnon, 2015).

The demand for road fuel is a derived demand for energy services in road transport. This means that there is intermediate demand for transporting goods and people that is met through a combination of capital, labor, and fuel. Increases in the demand for freight transportation has globally driven road fuel consumption. As a counterbalance, the promotion of energy efficiency has become a key energy policy mechanism around the world to tackle the increased fuel consumption and emissions, and countries and regions have adopted different targets and policies to achieve energy and environmental objectives.

In the European Union, where transport accounts for 25% of energy-related GHG emissions (Walnum et al., 2014), the European Commission has passed specific directives for the sector. Since the introduction of the Council Directive 88/77/EEC in 1988 and followed by other legislation, the implementation of “Euro” standards since 1992, and the 2001 White Paper on transport, the energy consumption reduction objectives have been partially achieved. The goal has been to reduce GHG emissions by 80%–95% below the 1990 levels by 2050. However, the Commission has recognized that the specific targets for the transport sector needed to be adjusted downward to 60% due to the complexity of the sector (European Commission, 2011; Walnum et al. 2014).

In the case of the United States, trucks represent 6% of emissions and by 2030 these are expected to be greater than the emissions from light-duty passenger vehicles (Leard et al., 2016). The general approach to limit the emissions of the sector has been through the regulation of GHG emissions rates and fuel economy standards proposed by the EPA and the NHTSA. The implementation of the latest phase of standards (Phase 2) covers the years from 2018–27. These performance-based standards (i.e., they are technology-neutral) are estimated to yield GHG emissions reductions of up to 27% in tractor trucks, up to 24% in vocational vehicles, 16% in heavy-duty pickup trucks and vans, and up to 9% in commercial trailers by 2027 with respect to Phase 1 standards (2014–18).

In general, fuel costs represent approximately one-third of the operating costs in the sector. This implies that, regardless of policy targets, freight operators have incentives to minimize fuel consumption. It is clear that the development and deployment of new and more efficient technologies from vehicle manufacturers is, along with operations/logistics, the main channel to achieve these environmental and energy objectives. However, as it has been discussed in this chapter, energy efficiency improvements can lead to changes in the demand for energy services that offset some of the expected energy savings and consequently, forecasts of energy consumption reduction may be overstated. As evidenced by the empirical literature, rebound effects can be a non-negligible issue in road freight transport. Fuel efficiency improvement reduces the cost of freight transport, which in turn makes transportation cost-efficient for more goods, for longer distances and at greater frequency.

Ignoring rebound effect can overestimate the benefits of energy efficiency policy, which can in turn lead to decisions such as the (over) allocation of public funds to ineffective environmental and energy policies. Policy makers need to take rebound effects into account for air quality, energy security and climate change policy reasons. A rebound effect different from zero implies that the expected proportional reductions in emissions from fuel efficiency improvements might not be achieved. Therefore, the policy goals to reach specific levels of emissions through fuel efficiency enhancements might need to be adjusted accordingly in order to compensate this effect.

Fuel use per unit of energy service in the road freight sector has declined over recent decades and this may be further encouraged in the future through different means. For long-haul transportation, one possibility is the deployment of high capacity vehicles such as megatrucks or European Modular System combinations. Despite the potential for fuel consumption and CO₂ emissions reduction of this type of alternative, the expected savings might not be fully achieved, if the rebound effect generates unexpected modal shifts, in the form of a higher modal share for road transport. At local level, a transition of freight transport from trucks to light vehicles may also be possible, which has been observed for cities such as London in recent years. There are different reasons for this trend, such as the relative lack of regulation governing light vehicle use compared to HGVs, the popularity of e-commerce and Just-in-Time deliveries, the growth in demand for express and parcels services or the impact of congestion (Allen et al., 2016).

Regarding fuels, the main alternatives that may take over the future of long-haul heavy duty are hydrogen, e-fuels (i.e., synthetic fuels from renewable sources) and electrification. In particular, one of the most envisaged future scenarios for a decarbonized sector is one in which EVs or electrified road/transport systems take place. This is happening for the case of urban delivery. An electrified sector could imply a reduction in GHG emissions and local pollutants without any decrease in freight activity and avoiding concerns about rebound effects. However, this solution is likely to be affected by other considerations, such as the capital costs of EVs, investment in infrastructure (e.g., EV charging stations or electric roads) and the management of the electrical grid. Ultimately, energy-mix will be paramount in this paradigm, since for this solution to become effective, electricity should be generated from low-carbon energy sources.

There are other scenarios in which freight transport demand may be affected by the development of new systems or technologies. However, in most cases it is still unclear how likely it is that these developments will effectively happen and their chances of becoming “game changers.” For instance, despite the attention that 3D printing attracts, recent research is still inconclusive about its role and long-term impact on logistics. Another prospect is a setting of highly integrated energy systems, called ESI in the specialized literature. ESI is a relatively new concept that is still under discussion and will require policy and regulatory frameworks to be rethought across different

sectors of the economy. A paradigm, which seems easier to be implemented, is the development of integrated transportation demand management. This encompasses different transportation options and infrastructures to optimize the logistics of all modes in the transport system, which can become a relevant means to reduce and redistribute the transport demand.

Finally, it should be noted that due to the scarcity of empirical studies and limited understanding of the rebound effect in freight transport, further research is still needed. The evolution and magnitude of the rebound effect arising from higher energy efficiency in the sector is relevant from a policy perspective to assess the effect of energy efficiency improvements and national and international energy and climate policies. So far, the results from the literature have evidenced that rebound effects can be of sufficient magnitude to be explicitly taken into account in policy design. These results are of direct policy relevance given that fuel efficiency standards are among the main policy regulations to reduce environmental effects in the commercial transport sector and especially for heavy-duty trucks. In order to assess the effects of fuel economy regulation, information about the rebound effect should be based on analyzing data series of different countries. If efficiency standards fail as pollution control tools, then other measures such as fuel taxes, carbon taxes, feebates, or cap and trade programs could maintain a prominent role in climate policies, in addition to other measures.

Moreover, it should be noted that even when the “relative” magnitude of the rebound effect is low, the environmental impact of foregone reductions from efficiency improvement could be significant, due to the scale of the transport activity and the marginal cost of the externalities in some countries. The rebound effect is a potentially relevant factor and it is, therefore, important to consider specific policies that ideally can be combined with price signals in the sector, the promotion of intermodality and, where feasible, the provision of alternative and environment friendly means of transport.

Introduction

Freight transport's task is overcoming space as a function of production and consumption. The transport of goods becomes necessary because the places where goods and services are produced or provided and the places where they are consumed are rarely identical. The same applies in the case of people who are transported to their place of employment for the purpose of providing a service; craftsmen for example need to carry tools or components with them. Therefore, in contrast to the mobility of individuals, freight and commercial transport is not a question of mobility per se, but develops as a consequence of the spatial and functional division of labor in systems of production and ways of life. This brings about certain transport requirements for commodities, goods, auxiliary materials, and operating supplies as well as for personnel. For this reason, technological development in the area of automated freight transport has been distinct from that of passenger transport.

The trend toward greater automation has long been evident in all modes of transport. Remote control is being used in the case of driverless railways, and the autopilot has been the norm for steering aircraft for quite a while. The first Unmanned Aerial Vehicles (UAVs—commonly referred to as drones) are already flying in the civilian sector and being used for inspections, surveillance and surveying or for film productions or the transport of small consignments such as pharmaceuticals. Drone ships are being developed where, for example, a crew is only aboard when the ship is in port. Unmanned submarines have been in service for quite some time. All modes of transport have different degrees of freedom, which are partly dealt with in other chapters of this encyclopedia.

This contribution aims to create an understanding of autonomy in the realm of transport. For that purpose, automated solutions already implemented in the area of freight transport are outlined, and the effects in the area of the supply chain and road transport system are critically reflected. The article sums up with some conclusions and makes recommendations for further research.

Autonomy in Freight Transport

Autonomy is a state of freedom of decision and action, and it is usually equated with self-determination, autonomy and independence. While these concepts can be understood by everyone in the context of the mobility of individuals, the question arises as to what this means for the mobility of goods.

There are different approaches that can be distinguished by degree of automation of spatial mobility. First, it can be differentiated with respect to the degree of automation of the driving task itself, of the vehicle and as concerns the benefits of mobility. The driving task itself consists of steering, accelerating and braking to achieve the desired vehicle movement. For this purpose, decisions are made about speed and lane selection, that is, the longitudinal and lateral guidance of the vehicle. Decisions required to carry out the driving task are made on the basis of information about the environmental conditions and associated knowledge of how to act in response to these conditions.

Autonomy of the vehicle, therefore, means handing over decisions about one's own driving behavior to the vehicle itself. Here, the autonomy of the driving task and the vehicle are closely interrelated. Donges (1982) differentiates the classical driving task assumed by the driver on three levels, according to the required information and action knowledge about the behavior of the vehicle and the environment: At the stabilization level, information about the road surface is a prerequisite for a decision on possible corrective measures. The same applies to the traffic situation at guidance level. Without driver assistance systems, the driver must contribute to keeping the vehicle in a controlled condition by changing the speed, lane selection and lane position. At the navigation level, information on the condition of the road network, on the traffic and environmental situation and their possible effects is

processed, in order to allow for a permissible, safe (or also fast or ecological) route selection. Then related action strategies will be derived.

In the field of road traffic, internationally recognized classification systems have been introduced by the German Federal Highway Research Institute (BASt) (Gasser, 2012, p. 9), the American National Highway Traffic Safety Administration (NHTSA, 2013, p. 4–5) and the Society of Automotive Engineers (SAE International, 2016, p. 19–24). In the meantime, the DIN (German Institute for Standardization) and the SAE International have been working together to promote an internationally uniform understanding of the autonomy of road-bound vehicles. Most recent definitions, such as those of SAE International, assume an automated vehicle (AV) as a vehicle equipped with driving automation technology (DAT) on levels 1 to 5. At present, there are usually six levels of automation considered, including level 0 which describes the vehicle without any assistance. However, the differentiation of the various levels has not yet been finalized. In principle, the different steps toward fully automated driving differ primarily in their functional scope, that is, how many subtasks the system performs for a certain period of time and in specific situations. The driver is considered to represent either a fall-back level or a control organ.

The autonomy of vehicles starts at the level of stabilization and track guidance. The driver's use of the vehicle is facilitated by the installation of technical components that compare target values and actual status, then trigger independent corrective measures. In order to further increase the safety and comfort of vehicle use and the driving task, driver support features and automated driving features were developed, which can react in response to specific conditions or situations. At a lower automation level, the vehicle is thus able to detect, for example, the vehicle in front or stationary objects. Typical examples of features of the first automation level of traffic flows are the lane-keeping assistant and adaptive cruise control. When several of these features are installed, usually Level 2 is ascribed. Up to this level, reference is made only to the Data Sharing Framework. At Levels 3–5, automated driving features are installed. ADF not only support the driver in the correct execution of the driving task at the stabilization and lane guidance level, but also make decisions at the navigation level. AVs starting at Level 3 are able to recognize moving objects, which can also be subjects, and formulate decisions and actions depending on the road conditions (e.g., black ice, construction sites) or environmental conditions (e.g., heavy precipitation, snow). At lower speed ranges, these conditions will usually trigger an immediate braking action. The parking assistant for example, which is already available today, is able to carry out steering movements automatically in manageable environmental conditions.

At higher speed ranges, the decision-making process is usually much more complicated and often more complex. This is mainly due to the information required on environmental conditions, the complexity of which is influenced on the one hand by the performance of the technical systems required for environment recognition and interpretation range of the situation assessment interpretation, and on the other hand by possible feedback loops between the different subsystems. In particular, the decision algorithms for action preparation in complex environments must take into account not only the target variables of safety and comfort for the vehicle occupants, but also ethical aspects, in particular with regard to the evaluation of other road users, living creatures or objects.

Until now, no worldwide ethical standards apply. The first ethical rules on “automated and networked driving” were presented for the first time by an independent commission in Germany in July 2017. In the meantime, this initiative has been transferred to the European Union level, in order to develop a common standard. To date, there seems to be an international consensus that in the case of passenger transport, individual autonomy is valued so highly that the driving task must always involve human drivers, even in vehicles that have the autonomy level of automation.

Only from Level 4 onwards can the specific case of application involve the omission of components, which allow a human being to accelerate, brake and steer the vehicle. Level 5 stands for vehicles that can move without a driver in all situations and describe the term autonomous. As far as ethical values speak against vehicles without components for human driving in individual traffic, such solutions are only being used for the transport of goods in demarcated environments. In the field of freight transport, the main benefit lies in overcoming the distance between goods production and consumption. From a logistical perspective, greater vehicle autonomy aims above all at optimized economic and ecological efficiency. In addition to safety aspects, aspects such as time, reliability, predictability, etc. are also taken into account during system design and can be evaluated differently, depending on the application.

Since conditions and applications for an autonomous vehicle on public roads are not yet fully known, these are described using scenarios. A scenario consists of a sequence of scenes, which describe a current situation where at least one dynamic element, for example, steering, changes its condition because of an activity, for example, parking, takes place (Geyer et al., 2014). Selected scenarios for freight transport are outlined in the following sections.

Automated Transport Systems in Closed Environments

Even before industrialization or the invention of the steam engine, transport systems, which relieved people of the burden of transporting typically heavy bulk goods, were developed. With the emerging functional division of labor across different factories and localities, the need for transport between processing steps increased. At the same time, an increasing management focus on technology came to envisage a complete automation of repetitive labor. While economic situations varied, this vision was largely driven by a mixture of labor shortages, efficiency concerns and reliability aspects. More recently, in-house conveyor (belt) systems, initially adapted from bulk goods transport, were integrated into the production flow. They were placed between the production and assembly stages and in incoming and outgoing zones, in the picking zone and also in the warehouse area.

The increasing flexibility of the production systems led to a growing demand for a flexible and reliable material flow. The first automated guided transport (AGT) systems were introduced in the early 1950s. AGT systems consist of a control system specifically for order placement and route planning, a communication system and vehicles. The name AGT is derived from the fact that there is no driver on board, and the transport order processing is carried out via a control system. This control system handles the central management of transport orders, vehicle-scheduling and order-processing. The traffic control system is similar to that for rail traffic in block sections, where only one vehicle is allowed to move in a particular section. Newer approaches to decentralized control rely, for example, on cooperative, agent-based negotiation processes between vehicles, or use biomimetic approaches, such as swarm intelligence, particularly for route planning and order placement.

In the past, physical guidelines were used for vehicle positioning, such as magnetic tapes, active-inductive, or optical guidance tracks. Metallic or magnetic ground marks or transponders are used for grid navigation. Newer technologies combine laser scanners and camera systems with digital environmental maps and enable free navigation by means of environmental features. This means that existing reference points can be used without committing to major investments in additional infrastructure. The AGTs will be equipped with 3D lasers, laser scanners and cameras for 3D environmental detection. Security concepts also increasingly work with sensors and laser scanners. However, they are limited to a minimum functionality, since the operating speed is at low levels, and the scenario is controlled.

Automated Transport Systems in Open Environments

Typical areas of application for driverless vehicles outside of plant premises are, for example, AGT for heavy transports or internal shuttle transports. One of the oldest examples are automated guided vehicles (AGVs), which transport containers between the container gantry cranes and the container warehouse, for example at container terminals in the port of Hamburg, Germany. The AGV's position is determined by transponders, and route planning is carried out independently, as is battery replacement. The system is controlled via radio data transmission. Driverless truck systems operate according to similar principles on factory premises between production and logistics buildings, often combined with automatic loading and unloading devices. In outdoor areas, the safety concept usually consists of radar sensors, with an increasingly frequent use of laser scanners.

Automated trucks have been used for even longer to transport raw materials in mines. Navigation is now carried out using radar and laser technologies and waypoints for orientation. Control and intervention options are implemented via a control center and in smaller environments by wireless LAN. In bigger areas GPS and dead reckoning are used through ongoing positioning (localization) which measures course, speed and time, as with a ship or aircraft. In addition, so-called driving robots have been developed for use in dangerous or difficult-to-access situations. A German logistics service provider, Hermes, has already tested so-called starship-delivery robots.

Future Scenarios of Autonomous Freight Transport

As the aforementioned remarks have revealed, driverless freight transport already exists in many areas. When operating fully automated freight transport, including free navigation across the entire road system, a driver is certainly no longer present. As a consequence, personnel would be missing for fulfilling other activities in the supply chain, such as loading or unloading vehicles (see the following section). However, this scenario is rather unlikely to happen in the foreseeable future. Therefore the following solutions for road-bound traffic that are under development, or even already in use, are more likely to happen:

- The “autopilot” is already being tested as a form of highly automated driving on motorways with the driver available as fallback. The driving robot controls the vehicle between motorway access and exit, or in clear driving situations.
- The “platoon” on motorways consists of vehicles coupled with electronic drawbars that use their own (dedicated) electrified lane for safety reasons. In the first period, a fallback driver still steers the lead vehicle.
- The “follow-me” semi-autonomous vehicle serves the user as a rolling depot for goods or tools when stops are close by. If necessary, the user jumps on the vehicle and steers it. In the approved scenario—for example, a city center delivery at low speed—navigation is remote-controlled by the user.
- “Valet parking or delivery” is the use case in which the driving robot on the “last-last mile” takes over the parking of the vehicle, or the docking of a truck at the receiver's ramp or navigation without a driver from, for example, a waiting zone to a large construction site. Depending on the environmental conditions, this would also be already possible to implement without the need for a fallback driver.

Process Changes in the Supply Chain through Automated Goods Transports

Increasing automation in road freight transport also triggers process-related changes in the supply chain, which can be trip-related, vehicle-related, load-related and supply-chain-related. In those automation stages where a person remains in the vehicle as a fallback level, it is expected that the range of activities will expand further. In particular, an increase in planning, documenting and controlling activities is anticipated. These activities may require at least some advanced training, in particular in the area of

Figure 1 Typical fields of activities of truck drivers. *Source: Adapted from Flämig, 2016*

disposition and controlling. However, completely new occupational profiles can also emerge. In principle, it can be expected that tasks will shift further from physical to (co-) thinking activities, which usually require a higher level of training and expertise. At the same time, more demanding technical knowledge and physical activities, such as vehicle inspection, load securing, etc., are emerging. The profile of the professional driver is likely to expand accordingly.

In the case of highly automated, driverless, or autonomous transport, the frequent problem of delays owing to traffic and waiting time would become obsolete and itineraries could be planned with a higher degree of freedom. From the perspective of the driver's current job profile in production and retail distribution, the so-called added-value services in particular must be reorganized. However, it is conceivable that the emerging driverless supply chains could also create low-skilled jobs. In addition to driving and vehicle inspection, many drivers also perform activities in the area of handling incoming and outgoing goods or picking inventory. Tasks such as loading and unloading of the vehicles will continue to be performed—if not by the supplier or transporter, then by the recipient. Delivery robots, which have already been tested in last-mile distribution, may transfer the task of the removal of goods to the recipient. It is also conceivable, however, that a further business model could emerge for logistics service providers. This could lead to a revaluation of logistics work in general, and the creation of more localized employment, especially in urban areas.

In the area of production, one could imagine that transport contracts will be put out to tender and autonomous trucks could “bid” for them, winning certain contracts according to predefined criteria. This would neither require central control nor pathfinding. As freight locks are already existing in practice, no physical staff would be needed to be present, in order to organize the goods transfer or to minimize risk. In general, this means that the framework conditions in which companies design supply chains need to be redefined, and new degrees of freedom must be introduced within associated design practices (Fig. 1).

Conclusions and Outlook

Automated driverless vehicles have been used for the transport of goods in raw material extraction, production and in closed logistics systems for a long time. Tele-operated driving often takes place when an operator controls the vehicle from a remote location. The transport of goods outside of, or between, companies takes place in transport systems in open environments, and this usually includes a driver, conductor, or pilot. An increasing automation of vehicles can be observed in road traffic. In vehicles with lower levels of automation, assisted systems, when engaged, warn the driver if the vehicle is not running safely. In the case of semiautomated vehicles, the system takes over control for a certain period of time or in specific situations (or both), in order to ensure the longitudinal and lateral guidance of the vehicle. Fully automated vehicles, on the other hand, can navigate freely, regardless of situation and infrastructure.

The relationship between fully automatic driving robots and forms of traffic controlled by human beings will become more interwoven over time. For the use of autonomous vehicles alongside road-bound traffic, the introduction of a higher-level authority is therefore conceivable, which can intervene directly in vehicles' kinetics, as already occurs in the case of internal driverless transport. By comparison, in existing air, rail, and sea traffic systems, higher-level means of control extend only to regulating traffic flow. The digitalization of the road infrastructure can, therefore, be assumed to be in an early stage of development. The automation of vehicles is primarily a technical issue with direct implications for the prospects of automating driving or transport tasks. Initially, it served only to improve the safety and comfort of manual driving, while more recent developments aim at the complete automation of the

driving task. However, analysis of possible developments in supply chains with regard to driving and transport tasks should go beyond the transport system per se. Gradual automation of individual logistics processes which, in their totality, may lead to an autonomous supply chain and may also mean that consideration of micro- and macroeconomic cost-benefit factors become relevant. For example, the lower safety buffers and more homogeneous driving speeds which can be achieved through automation may help to reduce energy consumption and to increase the capacity of existing road infrastructure.

Meanwhile road traffic has become more diverse. In addition to cars and trucks of different sizes and degrees of automation, (cargo) bicycles, trailers, or scooters such as Segways with e-drive are widespread. At the same time, parts of goods transport have shifted to drones or underground transport systems. Intermodal vehicles, such as the RiverBus in Hamburg, must also be considered in any future automation of road-bound transport. More and more structures and purely mechanical components are being replaced or supplemented by electronic components. Sensor technology, lasers and laser scanners, cameras, radar, and transponder technology are becoming an integral part of material flows of goods and commodities, transport and handling technology, supra-structures, and infrastructures. Infra- and supra-structures increasingly provide real-time information about their (expected) conditions, for example about potential accident hazards and traffic jams. With digitalized, smart infrastructure emerging, individualized end-devices (such as smartphones) may be able to communicate with other smart vehicles or other end-devices.

The integration of information flows across the entire value chain not only changes the predictability and, thus, the accuracy of material requirements planning. Rather, networked, decentralized, real-time-capable and self-optimizing production and logistics systems will become possible, with which small units can be produced at a higher degree of individualization than before. These smaller units may have just as much influence on the autonomy of goods transport as the generative manufacturing processes made possible by the computerization of production.

In further discussion about the automated flow of goods and automated vehicles, embeddedness into the cyber-physical system of logistic systems for goods and commodities must be kept in mind. The simultaneous emergence of autonomous systems in other transport modes, for example drones, indicates that completely new business models in the field of logistics can be conceived through the emergence of autonomous systems. In these systems, the flows of goods tend to be more granular, more individualized. However, a proper conceptualization and evaluation of these flows is as yet pending. Therefore the current way of introducing these new systems incrementally seems appropriate and realistic. In the course of this associated networking process, new partners, partnerships, new cooperations, or new commercial enterprises need to be integrated into the system. Testing of these developments in real-world settings should therefore be accompanied by appropriate implementation research, in order to minimize negative feedback effects in particular. Digitalization in the form of networking, robotics, and automation is likely to change the physical networking of transport systems and the transition from the logistics system to the transport system. It also changes networking in relation to the economic and social framework conditions. These different dimensions must, therefore, be considered together.

An Introduction to Rail Freight

This article presents a critical review of rail freight, split into two sections: an introduction to rail freight and a discussion of key opportunities and challenges facing rail freight in the 21st century. Within this introduction, rail freight activity is first defined and its role in the freight market is set out. Key commodities carried by rail are then elaborated and the fundamentals of rail freight operations are examined. The section concludes with a discussion of the relationship between the rail infrastructure and the provision of freight trains over that infrastructure.

What is Rail Freight?

At its most basic, rail freight comprises the movement of goods (as opposed to people) on railway/railroad systems. This is typically distinct from passenger train operations and involves dedicated freight (or goods) trains comprising one or more locomotives hauling a set of freight wagons. There are alternatives for certain flows; however, such as freight multiple units (e.g., those used by the Royal Mail in the United Kingdom (UK) or, until 2015, the dedicated high-speed TGV trains carrying mail in France for La Poste), passenger trains with space devoted to carrying small quantities of freight, or even combined trains conveying both passenger carriages and freight wagons. Where they exist, however, these alternatives tend to be niche.

While data are incomplete and not fully comparable, Fig. 1 shows that global rail freight activity is highly concentrated in just a few countries. While data sources do not always concur, UIC data show that the Russian Federation, United States, and China each account for 25%–30% of global activity and in combination have more than 80% of the total market. While Germany, the largest rail freight market within the European Union, has just 1% of global rail freight activity, some European countries, notably Germany and Switzerland, rank highly in terms of rail freight activity per capita, reflecting the importance of rail freight to their economies.

Rail's Share of the Freight Transport Market

It is generally the case that rail's mode share of freight transport has declined since the middle of the 20th century, in both developed and developing countries, mainly because of the growing competition from road haulage. In the United Kingdom, for example, rail's share of freight moved declined from 54% in 1953 to just over 8% in 2016, while in India, rail's share more than halved from over 80% in 1950–51 to around 35% in 2014–15.

In the three biggest rail freight markets identified in Fig. 1, rail's share varies considerably: Russian Federation (17%), United States (32%), and China (8%). Eurostat data reveal considerable variations between European countries in rail's share of the inland freight market (Fig. 2). In conjunction with the type of rail freight activity (Fig. 3), it can be seen that those countries with a higher rail share tend to be more integrated into international rail systems, with a dominance of international and/or transit traffic and a smaller share for national flows. Country size, geographical location, and industrial structure are important factors influencing rail's share of the market.

Figure 1 Worldwide rail freight activity (% of ton kilometers, 2017).

Figure 2 Rail share of inland freight transport (EU plus others, 2016).

Figure 3 Rail freight activity by type of transport for main undertakings (EU plus others, 2017).

Even in countries where rail's overall share of the freight market is relatively low, rail often plays an important role in certain markets. For example, around 45% of the land-based freight volume to/from the Port of Hamburg is moved by rail, and 40% of construction materials used in London arrives there by rail.

Typical Rail Freight Commodities

A high proportion of rail freight's costs tend to be "fixed," certainly in comparison with those for road haulage. To allow freight trains to operate, considerable investments in track, terminals, locomotives, wagons, and skilled staff must be made. As a consequence, rail is best-suited to high volume flows over long distances, since this helps to reduce unit costs and provides rail with a competitive advantage over road haulage. The commodity composition of a country's rail freight market is dependent upon numerous factors including economic structure, availability of raw materials, industry activity, and geography. Activity is usually dominated by bulk flows of raw materials (e.g., coal, construction materials, crude oil, grain, iron ore, timber) or manufactured goods (e.g., cement, chemicals, petroleum, steel). In the Russian Federation, for example, coal and oil and petroleum products comprise almost half of the tonnage carried by rail, while coal alone is around one-third of rail freight tonnage in the United States. In certain countries, including Australia and South Africa, freight trains carrying more than 20,000 tons of raw materials are commonplace.

Over the last few decades, intermodal techniques (e.g., for unitized loads such as ISO containers) have become more common, though their uptake on rail has been variable. For example, **Fig. 4** shows how the importance of intermodal rail freight has changed across the European Union between 2007 and 2016. In most countries where data were available for both years, intermodal rail freight as a proportion of the total rail freight market has increased. While it remains a minority of total rail freight activity overall, in some European countries, it was approaching a 50% share in 2016 and had already exceeded this in Ireland. In general terms, intermodal activity is a major growth area for rail freight, with rail focusing on its strengths and road haulage satisfying the requirements of the door-to-door journey of dispersed customers' consignments.

Fundamentals of Rail Freight Operations

In most cases, to be able to operate freight trains, the following components of the system are required:

- Locomotives—to provide the power to move the goods
- Rolling stock—the wagons in which the goods will be carried
- Staff—to crew the trains, load, and unload goods and provide administrative services
- Line-of-route infrastructure—to allow trains to move from A to B

Figure 4 Share of intermodal transport units in rail goods transport (Eurostat data—2007 and 2016).

- Terminals—to provide the interface between the rail network and the “wider world” (either suppliers’ and customers’ premises or other transport modes)
- Handling equipment—the means by which the goods are loaded on and off the rolling stock

In a basic sense, freight train operations can be categorized as either trainload or less-than-trainload/wagonload in nature. Dedicated trainload provision is the most straightforward type of operation, with a block train moving from origin to destination without any intermediate marshalling activity, generally carrying a single commodity type for a single customer. Intermodal rail freight can also operate on a trainload basis, direct from one terminal to another, though conveying unit loads of different commodities for a range of customers. At the other extreme, a true wagonload operation will permit the movement of individual wagons through the network on shared-user services, but often this is not an economically viable option. Where viable, though, it does provide a rail freight service for customers with smaller quantities of goods to be moved. **Fig. 5** shows an example of a

Figure 5 Examples of wagonload (left) and trainload (right) rail freight operation.

wagonload service on the left, with a range of different wagon types clearly visible behind the locomotive, and a bulk trainload service carrying only coal in large hopper wagons on the right.

The ideal freight flow attributes for rail are high volume, long distance, and predictability/regularity, since a combination of these plays to the strengths of rail transportation. As with wagonload services, there may be potential to combine several small volume flows into a long-distance trunk movement. While wagonload operation generally has been in decline in recent years, there have been attempts to reinvigorate it, such as with the Lineas (Belgian Railways) Green Xpress initiative which combines wagonload and intermodal flows into viable trunk trains between European hubs. Wagonload remains an important form of rail freight operation in many countries, such as Germany and the Czech Republic, but has been all but eliminated elsewhere (e.g., in the United Kingdom).

Relationship between Infrastructure and Service Provision

Rail network density is considerably lower than that for the road network, so door-to-door rail freight is not an option for many flows. Terminals are a critical part of the overall rail freight system, given that freight flows need access to, and egress from, the rail network, connecting with other modes of transport such as road or shipping. They can also be used for transferring freight from one rail service to another, but this is more usually carried out in marshalling yards. On the rail network itself, route characteristics such as axle weight limits, loading gauge, signal spacing and gradients will influence the maximum length and weight of freight trains which are able to operate.

Some countries' rail networks are geared toward freight activity as the prime (or sole) user, while for others, freight must compete with passenger traffic to gain access to the network. The operation of freight trains on a mixed-use rail network, such as in the United Kingdom and most other European countries, poses particular problems and often results in less than ideal journey times. Rail network capacity is fixed and freight trains require paths, or slots, in the timetable. Freight trains often receive less priority than do passenger trains, and are perceived (sometimes rightly, sometimes not) as being slower. This need for scheduling can reduce rail's flexibility, particularly where there is little spare network capacity, but can also lead to robust and reliable service provision, since capacity must be available for a train to operate. This contrasts with road haulage, where network access is typically less controlled, offering greater service flexibility but also an increased risk of being delayed by congestion. Owing to capacity constraints, freight trains are sometimes limited to off-peak operation only, held in passing loops to allow passenger trains to pass, or diverted along more circuitous routes where spare capacity exists. Such treatment of freight traffic may not encourage new customers, whose requirements may not be compatible with the constraints imposed by such network access, or lack of it. Even on freight-only routes, line capacity may be limited because of low operating speeds and long single-track sections where trains cannot pass. In addition to line capacity, terminal capacity may be a constraining factor.

The respective involvement of governments and the private sector has varied over time and in different parts of the world. There is often a distinction between the provision (and maintenance) of the infrastructure and the operation of services over that infrastructure. The main models are vertical integration, where both infrastructure and service provision are the responsibility of one organization, and vertical separation, where infrastructure is managed by one entity and one or more operators provide services over the infrastructure. The USA has a vertically integrated system whereby private railroad companies own the infrastructure and provide services over it. In contrast, China has a vertically integrated system, which is state-owned and operated. European rail operations have moved toward vertical separation, with generally state-owned infrastructure with competitive service provision, often a mix of public and private sector. Competitive issues are considered further in Section Competitive Markets Within Rail Freight.

Key Opportunities and Challenges for Rail Freight in the 21st Century

As with any other freight transport mode, rail has both positive and negative attributes, which present opportunities and challenges when it comes to satisfying contemporary transport requirements and in responding to the wider economic, environmental and societal issues associated with freight flows. This section discusses some of the key issues affecting rail freight.

The Changing Nature of Supply Chains

Wider changes in supply chain activities influence both the total demand for freight transport and the modal split of this demand between the various transport modes, providing both opportunities and challenges for rail. Globalization has led to greater specialization of production, more supply chain complexity and an increasing average distance between the points of production and consumption. In some cases, where flows have become more frequent, time-sensitive and dispersed, rail is disadvantaged, since it is generally less flexible than road haulage and is perceived as being less customer-responsive. Where manufacturing activity has been transferred from the long-established industrialized nations to cheaper and less-developed countries, such as from western Europe to southern and eastern Asia, freight transport requirements in the industrialized nations have witnessed a decline in bulk flows of raw materials and semimanufactured goods, typically well-suited to rail, and a growth in dispersed flows of consumer products, for which road haulage is generally more capable.

However, there have also been changes which have worked in rail's favor. For example, the trends toward globalization and containerization have led to increased volumes needing to be moved between major ports and suppliers/customers located within their hinterland areas, feeding into and out of deep-sea maritime services (such as at the key European container ports of Antwerp,

Figure 6 Number of China Railway Express (CRE) trains operated (2011–Sep 2016).

Hamburg and Rotterdam). In some circumstances, notably between China and the European Union, rail has begun to offer a direct alternative to sea and air; **Fig. 6** shows the rapid growth of such provision between 2011 and 2016.

Information and Communication Technologies (ICT) for Rail Freight

Rail has a long history of developing internal ICT systems to monitor and control the movement of freight trains since access to, and movement over, the network tends to be highly disciplined and signaling systems keep track of train movements. Key applications include establishing the position of trains on the network, identifying which locomotives and wagons are included in a train, recording the commodities carried on each train or wagon, and determining maintenance schedules and requirements for the rolling stock. While these are important uses, their benefits are often not shared with customers. This leads customers to complain frequently that their consignments disappear into a “black hole” when on the rail network. An increasing focus on customer service by at least some rail freight operators is seeing the diffusion of ICT to include the interface between internal systems and customers. Examples of operators introducing track and trace systems for their customers include CSX (USA), DB Cargo (Europe), KiwiRail (New Zealand), and Pacific National Rail (Australia).

ICT developments are assisting rail freight in other ways. Modern locomotives can be controlled more intelligently to provide more power at rail or to control other locomotives distributed through the train. In such ways, rail can play even better to its heavy haulage strengths. In a different application, remote-control shunting locomotives can improve the operations within a marshalling yard. More broadly, in-cab signaling offers potential to make better use of existing rail infrastructure, allowing trains to safely operate with closer spacings than is possible with traditional lineside block signaling. The European Train Control System (ETCS) is being developed as a means to better integrate the different rail networks across Europe with standardized technology and to contribute to operational efficiency improvements (see Section Perational Efficiency Improvements).

Rail's Contribution to Making Freight Transport More Sustainable

There is considerable evidence, which demonstrates that rail freight's impacts on the environment and society are lower than those of road haulage, its main competitor mode. On a normalized basis (i.e., per ton kilometer), rail freight performs relatively well when compared to the other freight transport modes, particularly road and air. As an example, **Fig. 7** presents the standardized UK government emissions of greenhouse gases for various freight transport modal options. Of course, these figures are averages, so it cannot be said that rail freight always outperforms road haulage; at the extreme, a diesel locomotive with a single wagon carrying 20 tons of goods would likely have a considerably worse impact per ton kilometer than would the use of a lorry for the same trip.

Figure 7 Freight greenhouse gas (CO₂e) emissions per ton kilometre, by mode (UK, 2017).

However, under normal circumstances, rail is considerably better than road per unit of transport activity when it comes to its contribution to climate change impacts and, as such, its use is often promoted in transport policies.

In addition to these existing environmental benefits, rail offers a faster route to freight transport decarbonization than is currently achievable for the other freight modes. In many countries, a high proportion of rail freight is electrically hauled already, increasingly using electricity generated from sustainable, carbon-free sources. In many cases where diesel traction is used at present, a switch to electric power can be achieved with relative ease.

Rail freight also outperforms road haulage when it comes to local air pollutants, with far lower emissions per ton kilometer of pollutants including particulates (PM10s), oxides of nitrogen (NO_x) and volatile organic compounds (VOCs). As the effects of air pollution have risen up the public health agenda, greater attention has been focused on the benefits of using rail freight in densely populated urban areas.

In an attempt to maximize the environmental and resource efficiency benefits, government freight transport policies tend to favor modal shift from road to rail. For example, the 2011 European White Paper on Transport set out a target for 30% of road freight travelling over 300 km to transfer to rail (and water) by 2030 and more than 50% by 2050.

Operational Efficiency Improvements

To make the most of rail's capabilities and to spread fixed costs more broadly, operators generally attempt to maximize the load carried on each train. **Fig. 8** shows that the freight load factor, essentially the tonnage carried per train, increased by an annual average of 1.2% across Europe from 2013 to 2017. Over a longer time period, from 2003–04 to 2017–18, the average freight train load increased by 63% in the United Kingdom. The increase by 2012–13 was actually 89%, but then dropped back as a consequence of the dramatic decline in heavy coal traffic. This demonstrates the importance of the commodity mix in influencing average freight train loads, since bulk trains of coal or aggregates tend to be heavier than intermodal trains.

Improving rail freight efficiency on a mixed traffic railway is a particular challenge, since both passenger and freight trains have to co-exist on the same infrastructure. Where the provision of passenger train services is intensified, freight activity can be marginalized. For example, slower freight trains may have to stop more frequently to allow faster passenger trains to overtake, lengthening journey times and reducing asset utilization for freight operators. To this end, the European Union is pursuing an initiative to develop priority corridors for rail freight, with greater international cooperation, enhanced train pathing and an overall aim to improve rail freight performance. In conjunction with the implementation of ETCS (see Section Information and Communication Technologies (ICT) for Rail Freight), it is hoped that this will make rail a more cost-effective and efficient option for customers and, as a result, lead to an increase in its share of the freight market.

Figure 8 Freight load factor (IRG-Rail data for 26 European countries, 2013–17).

Competitive Markets Within Rail Freight

While rail predominantly competes with other modes of transport for a share of the freight market (see Section Rail's Share of the Freight Transport Market), a switch from monopoly state provision to on-rail competition has become more common in certain parts of the world, notably the European Union. Over the last two decades, the rail freight market in the European Union has been liberalized and on-rail competition has been encouraged. While the process of liberalization started at different times in different countries, and has developed at differing speeds, [Fig. 9](#) shows that the domestic incumbent share had decreased to around 40% by 2015 across the sample of IRG-Rail countries included. In just a few small rail freight markets was there no competition, while most countries had a range of operators competing with each other, comprising new operators (i.e., nonincumbents) and, in many cases foreign incumbents, notably Germany's DB Cargo which has expanded into many other European countries.

Analyses of rail freight liberalization in Europe, for example, the IBM Rail Liberalisation Index and a CERRE study of rail freight regulation, have provided evidence that those countries, which are most advanced in the liberalization process have greater on-rail competition and, typically, have seen rail fare better in competition with other freight transport modes.

Innovation

In addition to those already discussed, several other initiatives have been developed to try to increase rail's flexibility and reduce costs and time to make it a more competitive option for end-to-end journeys. For example, transferring goods to and from rail at terminals can be time-consuming and costly, so new loading and unloading techniques have been introduced: in intermodal rail freight, new wagon types offer the ability to quickly transfer road semi-trailers between modes without the need for expensive lifting equipment.

There is a movement in support of the development of unconventional rail freight, as a means of making rail more competitive for smaller volume flows in the final stages of the supply chain. For example, research has been conducted into the potential for freight multiple units (FMUs) to offer a rail solution for smaller volume flows, but the uptake to date has been extremely limited.

More broadly, the European Union has invested in innovation through its Shift2Rail initiative, aiming to introduce new technologies and working practices to improve rail's competitiveness. Examples include new composite materials for lighter weight and more energy-efficient rolling stock and seeking examples of best practice in life-cycle costs for rail infrastructure and rolling stock.

Summary

Rail plays an important role in meeting the freight transport requirements of many different markets, both geographically and commodity-wise. While it does not offer the flexibility of road haulage, rail is well-placed to benefit from the increasing distances

Figure 9 Market shares of domestic incumbents, foreign incumbents and nonincumbent rail freight undertakings (% of train km in IRG-Rail countries, 2015).

over which goods travel in a globalized economy and where concern for the environment is increasing. It is important that policy makers support rail, though, as it can be challenging to increase its use given the prevailing economic and regulatory circumstances.

Introduction

On railway lines around the world, there are great numbers of various types of freight trains in operation. A freight train consists of multiple vehicles connected in a series that generally operates on a railway track and transports cargo or goods (Cole et al., 2013; Wu et al., 2017). The word “train” has been transformed from the Old French word “trahiner,” which can be translated as “to pull” or “to draw.” Freight trains usually consist of a mix of different types of rail vehicles. Most rail vehicles in freight train consists are unpowered and they are generally referred to as “wagons” in most countries in the world and as “cars” in the United States. In this article, all unpowered freight rail vehicles will be referred to as wagons. The term “wagon” can be defined as an unpowered rail vehicle that is used to transport various types of cargo and its design is significantly dependent on the type of cargo that it is designated to transport, the train consist that it will be hauled in, and the standard of rail infrastructure that it will operate over. Wagons in a train consist are generally hauled by one or more powered rail vehicles, called locomotives, that use motive power to haul cargo and goods to the destination point. The word “locomotive” originates from the two Latin words “loco” and “motivus,” which mean “from a place” and “causing motion,” respectively. The term “locomotive” has been strongly used to define this type of rail vehicle since the first locomotive building process that can be dated to the construction in Cornwall in 1801 by Richard Trevithick of his high-pressure steam locomotive engine “Puffing Devil” designed to run on roads. However, transport of railway cargo began with the application of the first practical freight locomotive in 1814 by another British inventor, George Stephenson, with his locomotive named Blücher hauling eight wagons loaded with coal, a total load of 30 tons, on a railway track up a gradient of 1 in 450 at a speed of 6.4 km/h. From that moment, rail cargo operations have strongly relied only on adhesion between rails and wheels.

The following sections provide an introduction to the classification and design of locomotives and wagons with a focus on existing modern designs, and then the principles of their operational application in train consists are discussed with details of the practical configurations in use for hauling the long and heavy modern freight trains.

Locomotive Classification and Design

The proper way to classify freight locomotives is to consider the energy sources used for their motion process. At the uppermost level, there are only two groups in use: nonautonomous and autonomous. A nonautonomous locomotive usually requires energy to be provided from a power source that is located outside the locomotive. A good example of this is an electric locomotive. An autonomous locomotive generates energy from its own power plant mounted directly inside of the locomotive and uses the generated energy for its motion process. Good examples of modern autonomous locomotives are diesel and gas turbine locomotives. Both groups have their own advantages and disadvantages. However, the main advantages of nonautonomous locomotives are a possibility to realize higher traction and to use energy in a more efficient way. The main advantages of the autonomous locomotive are that it does not need a very expensive electrical network infrastructure and it is very mobile in its application on the railway network, that is, it can be used on powered and non-powered railway lines.

It is possible to extend the classification further based on the type of power supply, and the modern freight locomotives are then divided into four groups (Spiryagin et al., 2014, 2017a; Steimel, 2008):

- Electric;
- Diesel;

- Gas turbine; and
- Hybrid locomotives.

An electric locomotive receives electricity from a power station to support its movement. The electricity generated by the power station is transmitted through high-voltage distribution lines to traction substations. The latter perform the transformation of the transmitted electricity to the parameters (voltage, current type, frequency, etc.) required to power traction and other equipment installed in electric locomotives. The transmission of the power from a traction substation to the locomotive pantographs is performed through overhead line equipment. An example of a general equipment layout of an electric locomotive is shown in **Fig. 1**.

A diesel-powered locomotive is commonly equipped with an internal combustion engine as a power plant, typically operating on diesel fuel or, in a limited number of countries, liquefied natural gas. The latter requires the installation of an additional tank for storing liquefied natural gas on the locomotive or it might be attached as a separate wagon adjacent to the locomotive (or shared between two locomotives). An example of a general layout scheme of a diesel-electric locomotive is shown in **Fig. 2**.

Gas turbine locomotives are equipped with a gas turbine as a power plant. This type of locomotive has not found wide application in freight operations yet due to the noise and heat produced during the motion process. However, their design scheme has potentially significant advantages in power density and the cost of fuel, and it is a particularly appropriate design for long-distance trips and extreme cold weather conditions.

Hybrid locomotives, which are similar in design to diesel locomotives, are equipped with an additional energy storage source(s) (electric batteries, supercapacitors, or flywheels) along with a diesel engine (Spiryagin et al., 2015, 2017c). The energy storage source is charged from the diesel generator during locomotive operation when some power is not required for traction purposes, and/or from the locomotive braking process where kinetic energy is transformed into electrical energy. It is a very efficient way to manage

energy resources. However, the freight hybrid locomotive designs are still only at the prototyping stage due to the significant costs of hybrid power and energy storage equipment along with the associated additional operating costs.

A further breakdown of the classification of freight locomotives might be done by types of use. There are only two groups: freight service and heavy haul operation. The main difference between these is that heavy haul freight locomotives are designated to haul very long trains with extreme axle loads and these types of locomotives can be commonly found on iron ore, coal, or other mineral traffic railways.

The general design classification of freight locomotives can be systematized as follows (Spiryagin et al., 2014, 2017a):

- By gauge of the track: There are a lot of different gauges in the world, but the main gauges of the freight railways in most countries can be divided into three gauges: “narrow gauge,” “standard gauge,” and “broad gauge.” The standard gauge of 1435 mm (4 ft 8 1/2 in) represents approximately 60% of global railway track length at the present time.
- By speed: There are two common groups—regular freight and high-speed freight. The latter is still not common these days.
- By an envelope that represents a limiting rolling stock outline: In other words, this limits dimensional characteristics of rail vehicles in order to allow them to operate on designated railways.
- By maximum power of the locomotive: There are commonly two characteristics in use—power generated by the power plant (e.g., engine) and the traction power delivered to the wheels. The difference in these characteristics is that the power plant power shows the maximum power produced by an engine only and does not take into account any losses in transmission systems. As a result, it means that the total power at the wheels is undefined, but it is clear that the power at the wheels is slightly lower than that generated by the power plant. The traction power much more closely reflects the real world because it shows the available traction power or force applied tangentially from all traction wheels to the rails. The values of power are usually presented in horsepower or kilowatts units. The power of freight locomotives is commonly positioned in the range from 2000 hp to 6000 hp.
- By the car body design, which might be classified as the cab unit or the hood unit and, at the same time, by the number of driving cabs, that is, one-cab or two-cab designs as shown in Fig. 3(A).
- By the number of units in a locomotive set: Common designs for freight locomotives can have from one to four units. In multiunit locomotive designs, a unit without a driving cab can be present and such a unit is commonly called a booster unit. In the general terminology, a driving cab unit is defined as an A unit, as shown by the examples in Fig. 3(A), and a booster unit is defined as a B unit. An example of a locomotive set with three (A-B-A) units is shown in Fig. 3(B).
- By the wheelset/axle vertical loads: These characteristics are critically important because avoiding any track damage or derailments requires that the maximum loads allowed by the track design are not exceeded.
- By the set-up of driven axles/wheelsets: The International Union of Railways (UIC) classification of locomotives has traditionally been used to specify the arrangement of axles within the same bogie (truck) starting from the front end of the locomotive by alphabetical symbols for the number of consecutive motorized axles (A for one, B for two, C for three, etc.). The use of a lower case “o” as a suffix after the letter is also in use to indicate an individually driven wheelset, that is, a wheelset that has its own separate traction motor.

Figure 3 Types of locomotive sets. Note: (A) one- and two-cab locomotive designs; and (B) three unit locomotive set with a booster as the middle unit.

- Locomotives usually consist of the following basic systems for the energy source (power plant): mechanical, electrical, pneumatic, and hydraulic. However, in terms of general design, locomotives are commonly classified by their components as follows: locomotive car bodies and frames, bogies, traction drives, suspension systems, and brake systems.

The car body of the locomotive is designed to accommodate the driver/s and various items of system equipment and components, and it must be able to cope with the application of all external and internal loads. It is commonly designated in two variants: a mainframe design where the frame is considered as a load-bearing component and a monocoque design. The latter integrates the body shell and the mainframe into a single structural element designed to resist all loads acting on it.

The bogies are used in a rail vehicle design to improve the dynamic performance of a vehicle in curved track sections. Depending on the design parameters of locomotives (weight, length, tractive effort, etc.) and restrictions due to loading gauge and axle load, bogies can be designed in two-, three-, and four-axle design variants. At the present time, the four-axle design is not commonly in use for freight train operations. However, it is more applicable for locomotives that are required to haul a long train over track that has axle load restrictions. Examples of designs of two- and three-axle bogies are shown in **Figs. 4 and 5**, respectively. The main elements of a bogie are the bogie frame, the braking system equipment, elements of the locomotive sanding system, spring suspension, and wheelsets with associated assemblies and traction drives.

The spring suspension can be divided in two systems—secondary and primary suspension systems. A locomotive frame/car body and bogies are connected with the secondary suspension system that supports the car body on the bogie frames. This system is commonly not a part of the system that is designated to transmit traction and braking forces from the bogies to the car body. In most locomotive design cases, special connection elements such as traction rods or a center pivot are in use. The primary suspension connects the wheelset or its axle boxes with a pair of bogie frames and is designed to minimize the effects resulting from dynamic interaction at the wheel–rail interface. Traction drives are commonly considered as part of a bogie in the freight locomotive design. The main purpose of traction drives is to transfer kinematic power from the traction motors through the mechanical gear transmission to the wheelsets. Various designs of drives exist, and they are commonly classified based on the design of wheelsets/wheels and the mounting methods of the traction motor. The traction drive design for freight locomotives is commonly customized for that locomotive type and operational use.

The main task of the brake system is the creation of an artificially controlled resistance force by a locomotive or train in order to reduce the speed or bring its movement to a full stop. Brake systems are divided into two groups based on the method used to create the resistance force, these being either friction or dynamic. The friction brake requires energy to be absorbed by the friction (brake shoes or pads), while the dynamic brake of a freight locomotive works on principles of transformation of kinetic energy of the

Figure 4 Two-axle locomotive bogie (manufactured by Ural Locomotives, Yekaterinburg, Russia).

Figure 5 Three-axle locomotive bogie (manufactured by United Group Limited, Newcastle, Australia).

locomotive or train into other electrical energy that can be dissipated, transmitted, or stored. The freight locomotive is also equipped with a parking brake that is designed to prevent any movement of a locomotive or train when it is fully stopped or parked on inclined parts of the track.

Locomotive Power Traction Systems

Electric traction systems are widely applied in freight railway systems. The drives are highly efficient, precisely controllable, and complex mechanical transmissions are avoided. The traction system consists of the following elements: a source of electrical energy—either an electrical overhead power system or an on-board generator, the power conditioning equipment, and the traction machines (motors).

Modern diesel-electric locomotives (Spiryagin et al., 2017b) use a diesel motor to drive an alternator/rectifier combination that provides electrical power for the traction system as shown in Figs. 6 and 7. Electric freight locomotives (Spiryagin et al., 2017a) are

Figure 6 Example of an electric traction scheme for a diesel-electric locomotive with an AC-DC topology.

Figure 7 Example of an electric traction scheme for a diesel-electric locomotive with an AC-DC-AC topology.

Figure 8 Example of an electric traction scheme for an electric locomotive with an AC-DC-AC topology.

normally supplied with AC power at 25 kV as shown in Fig. 8, but some 3 kV DC systems still exist. Both diesel-electric and electric locomotives can use either AC or DC motors.

AC motors, and generally squirrel cage induction machines, are the dominant technology choice for modern designs, but many older locomotives still operate with DC motors. The AC machine is much cheaper and more robust than the DC machine. The existence of affordable high-performance inverters and inverter control strategies allow an AC machine to be as easily controlled as a DC machine. The features of AC and DC machines are now discussed.

The DC traction machine best suited for heavy haul applications is the separately excited machine. These have independent control of the armature and field windings. There are two clearly identifiable operating regions. The low-speed or torque limited region applies from standstill to approximately one-third of the freight locomotive top speed. Above this, the high-speed operating region, which is also known as the field weakening or constant power region, occurs because of limitations on the motor voltages.

A freight locomotive will develop its maximum tractive effort in the low-speed or torque limited region. This is highly beneficial as the largest tractive forces are available from standstill to roughly one-third of the maximum locomotive speed. The motor field is maintained at its full rated current and the machine torque is limited by the maximum allowable armature current. In many locomotives, it is permissible to allow the motors to operate at higher currents for short periods. This allows even higher tractive forces for relatively short events such as climbing steep grades.

As the armature voltage is dependent upon the vehicle speed and the field winding magnetizing flux, there is a speed at which the motor voltage will equal the available source voltage. To operate at higher speeds, the field strength must reduce. This is the field-weakening region. The available motor torque, and hence locomotive tractive effort, reduces as the locomotive speed increases.

For DC motors, the torque and power are primarily controlled by adjusting the armature current. In a diesel-electric locomotive, the armature current is easily controlled by adjusting the on-board generator voltage through the control of the generator exciter winding. In an AC-supplied electric locomotive with DC motors, the armature circuit is supplied by a transformer and a thyristor phase-controlled rectifier. In both locomotive types, it is normal to have wheel slip control systems. If a wheel loses adhesion and wheel slippage occurs, the armature current will be rapidly reduced to regain adhesion. Adhesion control allows modern locomotives to produce the highest possible tractive efforts even in poor wheel-rail interface conditions.

A DC traction machine will have a rating up to several hundred kilowatts. Machines of this size have compensation windings or interpole windings to maintain the best operating conditions for the commutator. The commutator imposes a number of design constraints. The commutator diameter increases with voltage and the armature voltage will be limited to less than 1000V.

The AC traction machine most favored for modern heavy haul designs is the induction machine. The preferred machines are squirrel cage machines with four or six poles. These have no electrical connection to the rotor and no slip rings or commutators are present. AC traction motors will have power ratings in the range of a few hundred kilowatts to above 1 MW. The motor rated voltages will range up to 3000V and this allows lower currents.

The machines will be controlled by inverters that convert a DC power source into variable frequency AC power. Modern inverters generally use insulated gate bipolar transistors (IGBTs) but Gate Turn Off Thyristors (GTOs) are still found in some designs. The rotational speed of an induction machine is nearly directly proportional to frequency. Modern AC traction systems utilize

Field-Oriented Control (FOC) or Direct Torque Control (DTC) methods that provide precise control of the induction machine torque. An induction machine exhibits constant torque and constant power modes of operation that are very similar to those found with DC machines. At lower speeds, from standstill to up to about one-third of the locomotive top speed, the traction machines can produce their full torque capability. The machines operate with their rated magnetic flux and the torque is limited by the permissible stator and rotor currents. In the higher speed range or field-weakening range, the achievable magnetizing flux is limited by the available voltage. As the magnetizing flux falls, the achievable torque reduces.

The FOC and DTC control methods can provide very precise traction and adhesion control. Diesel-electric locomotives use a main generator to provide power to the inverters. It is normal practice to impose a torque rate limit upon the AC drive so that the diesel and generator combination is able to follow the changing demands in electrical power. For those locomotives that derive their power from an overhead system, rapid changes in tractive effort are possible.

Both DC and AC motors can provide dynamic braking. Both types of motors can be controlled to act as generators, and this provides a retarding force as the kinetic energy in the train is converted into electrical energy. An important benefit is the avoidance of wear in mechanical braking systems that rely on friction. This electrical energy must be either dissipated, stored, or returned to an overhead power system. The most common solution is to dissipate the electrical energy in braking resistors. These will often have ratings of a few megawatts. They can be mounted on the roof or within the locomotive in which case they will be force cooled using fans. In an electric locomotive, some power may be returned to the overhead power system. The amount of power that can be returned may be limited by voltage rises within the overhead power system. Electric locomotives will often blend the two approaches and regenerate some power into the overhead system and dissipate the remainder.

Hybrid traction systems use batteries or supercapacitors to capture some of the braking energy and store this for future use. Hybrid systems provide the most benefits in railway systems where braking is frequent. Braking occurs frequently in metropolitan passenger railways, but is less common in freight systems. In a freight system, the energy storage requirements can be several megawatt-hours, and this may require batteries with weights of tens of tons. Batteries can be integrated into the locomotive structure or an alternative solution is to use a battery tender that is a purpose designed battery wagon. Hybrid solutions are emerging but are not yet common.

Tractive Effort and Dynamic Braking Characteristics

The main performance descriptors for freight locomotives are generally based on their electro-traction transmission characteristics, which generally describe the tractive and braking capabilities of a locomotive and such characteristics are dependent on the train speed, adhesion conditions at the wheel–rail interface, and the load being hauled (Spiryagin et al., 2017a).

Locomotive tractive effort characteristics are usually presented by a graph of dependence between the tangential tractive effort and the speed at a given engine power (notch position of the throttle set by a driver). An example of characteristics for a diesel-electric locomotive is shown in Fig. 9. In this example case, the tractive effort characteristic also contains a restriction on the tractive effort due to the effect of an adhesion coefficient between wheels and rails, and the limit on the tractive effort set by the power plant.

Tractive effort characteristics of electric locomotives are different from those of diesel-electric locomotives in that the shape for the former is parabolic. An example of tractive effort characteristics of AC current electric locomotives is shown in Fig. 10 which displays

Figure 9 Typical tractive effort versus speed characteristics of a diesel-electric locomotive.

Figure 10 Typical tractive effort versus speed characteristics of an AC current electric locomotive for various throttle notch positions numbered 1 to N .

Figure 11 Typical dynamic braking effort versus speed characteristics of a diesel-electric locomotive.

different curves for different notch positions of the throttle (represented by the numbering 1 to N) which can be set by the locomotive driver.

Examples of dynamic braking characteristics are shown in **Fig. 11**. The figure contains three curves that represent different stages of the dynamic braking developments in locomotive designs. The modern curve is generally observed on modern AC freight locomotives, while the extended one is common for DC locomotives. At a low-speed range, less than 5–10 km/h, the traction motors cannot provide the required braking effort due to insufficient terminal voltages.

Freight Wagon Classification and Design

Large railway networks require a systematic freight wagon classification system to facilitate efficient rolling stock management. Freight wagon classification systems are commonly based on vehicle uses and mechanical designs. Again, as mentioned in the introductory section, different countries and regions can have different classifications under both methods, but common rationales can be seen within these different classification methods. A good understanding of any classification system can help to achieve an easier understanding of others. In this article, classifications used in Chinese Railways are taken as an example (Yan and Fu, 2008). Chinese Railways defines most of its wagons using 14 types, namely, box wagons (enclosed body), hopper wagons (open body), flat wagons, refrigerated wagons, tanks wagons, container wagons, ore wagons (bottom or side dump), oversize wagons (drop center

and Schnabel type), dangerous goods wagons, stock wagons (cattle), cement wagons, grain wagons, special wagons, and caboose wagons (becoming obsolete). Each type has its specific alpha registration code. For example, all tank wagons are registered with the initial “G” that is also the initial of the Chinese spelling for tank wagons. Individual wagons are then given unique numerical identifications.

Chinese Railways also categorizes different types of freight wagons into two categories according to their use as: (1) general-purpose wagons; or (2) dedicated-purpose wagons.

- General-purpose wagons include box wagons, hopper wagons, flat wagons, and refrigerated wagons. These wagons are designed to transport cargoes of a considerable number of different types. For example, a box wagon, as shown in [Fig. 12](#), has an enclosed cargo space and sliding side doors. It can transport many different types of cargoes such as bagged or boxed products, small machinery, and small items of merchandise: literally anything that can fit in the wagon.
- Dedicated-purpose wagons are those designed to transport a single or small number of types of cargoes. For example, a tank wagon, as shown in [Fig. 13](#), can transport only a small number of different types of liquid and liquefied gas cargoes such as acids, petroleum products, LNG, LPG, etc.

Bogie design is probably the most important part of the mechanical design of freight wagons. Discussions of freight wagon designs in this article are based on the different bogie designs. Currently, worldwide, there are mainly three types of freight bogie and running gear designs ([Iwnicki et al., 2015a](#)): (1) three-piece bogies, (2) Y-25 bogies, and (3) single axle running gear.

- A three-piece bogie ([Fig. 14](#)) mainly consists of a bolster, two side frames, and two wheelsets. The suspension system is a wedge-spring system in which the wedges generate friction forces to damp vibrations and impacts for the bogie ([Wu et al., 2018](#)).
- A Y-25 bogie is shown in [Fig. 15](#). It mainly consists of a rigid H-shape frame and two wheelsets. Flexibility of the bogie is provided by the suspension springs. A so-called Lenoir link is used for each quarter of the bogie to convert part of the vertical load into friction normal forces between a pusher and the frame. In this way, friction forces can be generated in suspensions to damp vibrations and impacts ([Vaghi et al., 2013](#)).

Figure 12 Box wagon—a general-purpose wagon.

Figure 13 Tank wagon—a dedicated-purpose wagon.

Figure 14 Three-piece freight wagon bogie. Source: From Wu et al. (2018).

Figure 15 Y-25 freight wagon bogie (brake rigging not shown).

- A single axle running gear is the oldest running gear arrangement used when no bogie design is needed in the freight wagon design. The UIC-Link Suspension design provides a double-link between the leaf spring and the wagon body that allows yaw and lateral movement of the wheelset for better curving performance (Jonsson, 2007; Ahmad, 2018).

Freight Train Configuration and Distributed Power

The concept of distributed power freight trains (Rail Industry Safety and Standards Board, 2018) is to use multiple numbers of locomotives or locomotive groups (commonly two or three) and place the locomotives at different positions along the train (head, middle, or tail) instead of placing all locomotives at the front of the train. Example of various distributed power freight train configurations is shown in Fig. 16.

The distributed power train concept was first put into service in the 1960s in the United States. It has two obvious advantages: (1) decreasing in-train forces during traction as the in-train coupler forces (Cole et al., 2017; Wu et al., 2017) are distributed at different locations along the train, as shown in Fig. 17. And (2) decreasing in-train forces and braking distance when slowing or stopping, as shown in Fig. 18. During braking, locomotives at the middle or the tail of the train act as extra brake initiating points that can decrease brake delays throughout the train and, in turn, decrease braking distance and in-train forces.

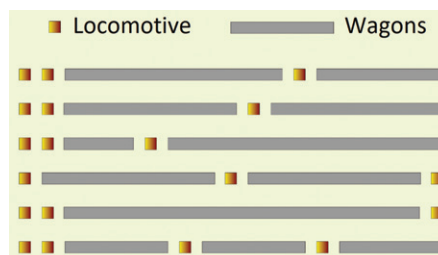

Figure 16 Example of distributed power freight train configurations.

Figure 17 Simplified in-train force distribution during traction.

Figure 18 Simplified brake delay distribution during slowing/stopping.

Driverless Freight Train Operation

Despite the apparent significant advances in autopilot and automated control systems for ground vehicles, examples of driverless freight train operation are rare. There are slowly increasing numbers of automated metro and airport passenger trains, so one could conclude that sufficient technology is available. Perhaps the best-known driverless freight train system is that of the Karratha Hamersley railway in the Pilbara region of Western Australia. As reported in [Briginshaw \(2018\)](#), a train route of over 400 km is now operating in driverless mode. This impressive rail system operates an average of 34 trains per day with train payloads typically greater than 28,000 tons.

Full automation of freight trains is complicated by the train length. Trains are the longest ground vehicles; small freight trains might be 400 m long, while state-of-the-art heavy haul trains may be as long as 4 km. The challenge posed for the control, either by a human driver or by an automated control system, is that the vehicle can be subject to several different operational conditions at the same time. In particular, the train can be subject to different speed limits and different curves and grades. In long trains, these forces from grades (gravity forces) can be transferred through the train to add to locomotive traction forces and braking forces and increase risks of train coupling failure.

Large freight trains also have very low power to mass ratios. This means that traction and braking will effect changes only slowly. Trains will take several minutes to get up to speed as the traction forces give limited acceleration. Dynamic and regenerative braking is similarly limited. Both traction and dynamic braking are limited by the friction at the wheel–rail contact, and so performance is limited by locomotive power, mass, and the rail surface conditions. The mass of the locomotive plays a role in the maximum performance, as the typical wheel rail friction coefficient will rarely exceed 0.5. Traction and dynamic braking are typically limited to forces less than 35% of locomotive weight to reduce the risk of slipping. To ensure reasonable stopping distances, all freight wagons are also fitted with air-operated brakes, but trains still take a long time to stop. Deceleration for a loaded freight train under full air braking is typically of the order of 0.45 m/s^2 (or just 0.05 g), which gives a stopping distance of at least 525 m from a speed of 80 km/h. If older brake technology is being used, stopping distances can be more than double this figure due to inherent delays in the way the equipment works. Suffice to say that trains, although guided by rails, are not necessarily simple to drive. Good train control requires forward planning of power and braking. The difficulty of this task increases with train length and with the difficulty of the terrain. Compliance with speed is, however, only one issue. Trains store a large amount of kinetic energy due to their mass. Unnecessary stops or reducing too much speed is an expensive waste of energy. On a typical trip, 10%–30% of the total energy is expended in braking. One of the incentives to automate train control is to save some of the energy due to improved or more consistent control. Energy saving from improved control methods is presented in [Yee and Pudney \(2004\)](#). A third issue is the coupling forces. Couplings are generally manufactured to a specified strength. As longer trains are marshaled, the drawbar forces increase due to the double or triple stacking of locomotives and increased gravity forces on grades. Once the train reaches a certain size, the locomotives need to be distributed in the train to reduce drawbar forces as was described in the previous section. On difficult

terrain, that is, on certain combinations of hills and valleys, it is sometimes necessary to use different locomotive controls in the different locomotive groups to reduce coupling forces and prevent train partings.

As control is not just a matter of speed compliance, driverless control of locomotives requires several sources of data and algorithms to replace the many thought processes and judgments made by a human driver. As a minimum requirement, the control system needs to have a full track database describing the topography, to allow gravity forces on grades to be assessed. The system needs speed limit information to ensure speed compliance. The system needs full details of the train mass, rolling resistance, curve resistance, and braking characteristics. Positioning systems such as GPS or suitable track signaling equipment is required to ascertain train position and, therefore, the track topography to be applied. The technology to enable these developments now exists.

Prior to the emergence of large driverless train systems, such as in Briginshaw (2018), several developments that give information, assistance, and advice to human drivers were developed. Many products and systems have been developed during the last 2 decades, noting the following systems: driver information (Hawthorne and Smith, 1998; Yee and Pudney, 2004; Cole et al., 2007), driver advice (Yee and Pudney, 2004), and cruise control (Cole and McLeod, 2004; United States Patent, 2008; Cole et al., 2009). No doubt, these provided the technical steps along the way to achieving driverless freight trains.

Conclusions

The optimization of locomotive and wagon designs, as well as of train operating configurations, are very important aspects in improving the efficiency of the railway land transportation market. The designs of powered and unpowered rail freight vehicles can vary quite significantly, and can result in major modifications to the design information presented in this article. The authors' intent in writing this article is to provide a basic knowledge on common freight vehicle designs and their classification. Powered rail vehicles were also covered in terms of the design of their traction systems and how to interpret their traction and dynamic braking design characteristics. In addition, the authors have placed strong emphasis on the various train configurations that can be found in real train operations around the world. The contents of this article are structured in a manner that allows readers to become acquainted with the common terminology used in the rail vehicle and train operational world. We hope that readers have found the information presented in an easily readable manner for the general public and that, at the same time, it is sufficiently comprehensive for railway practitioners. The references provided at the end of this article will allow readers to further explore the world of rail freight vehicles from descriptions of more detailed design issues and exploring some of the complex train operational problems that exist in freight railway systems.

Readers with enquiries regarding rail freight vehicle design or train configurations can contact the Centre for Railway Engineering at Central Queensland University by email at cre@cqu.edu.au or visit the website at www.cqu.edu.au/cre.

Introduction

The aim of this paper is to revisit the research study undertaken by Cranfield University in 2013 into the enablers and inhibitors of future growth for rail freight between Asia and Europe. In the last 6 years since the original research was undertaken, the volumes have grown exponentially with an increase of 7868% (Berger, 2017; Pomfret, 2018; Xinhua Silk Road Information Service, 2019; Zhang, 2017) in train movements from 2013 to 2018. It is now time to take another look at Eurasian rail freight and to address two key questions:

- Which enablers and inhibitors still exist?
- Which enablers and inhibitors have changed/emerged?

The British economist John Maynard Keynes advocated that in certain circumstances state intervention into an economy to encourage growth was essential. There are many notable examples over the years where the state has intervened in an economy by investing in capital infrastructure projects, which have been the impetus for future economic growth. They include Roosevelt's New Deal in the 1930s, the Marshall Plan at the end of World War II, and now recently China's President Xi Jinping's Belt and Road Initiative (BRI), which seek to improve land and sea corridors with China and the rest of the world. A key element of the BRI is the investment in upgrading the rail infrastructure that forms the Eurasian land bridge that links China with Europe.

The correlation between the introduction of the railroad industry and economic development can be traced back to the Industrial Revolution in the United Kingdom, with the introduction of the first steam powered freight railway in 1825 that carried coal between Darlington and Stockton-on-Tees. The global expansion of the railroad industry in the 19th and early 20th centuries and its relationship with economic growth is undeniable: a significant example is the Transcontinental Railroad in the United States opened in 1869. The railroad provided an important land bridge that enabled freight and passenger traffic to flow between the east and west coasts of America and facilitated growth at either end and the intermediate railheads along its route. Similarly, the Trans-Siberian railway (TSR) completed in 1916 established a significant land bridge between Moscow and Vladivostok. The BRI is now being heralded as an agent of economic development and a renaissance for the rail freight industry.

Enablers and Inhibitors of Eurasia Rail Freight

An investigation based on exploratory case-study research undertaken by Cranfield University in 2013, when traffic across the Eurasia land bridge was in its infancy, identified a set of enablers and inhibitors that would have an impact on the growth of freight

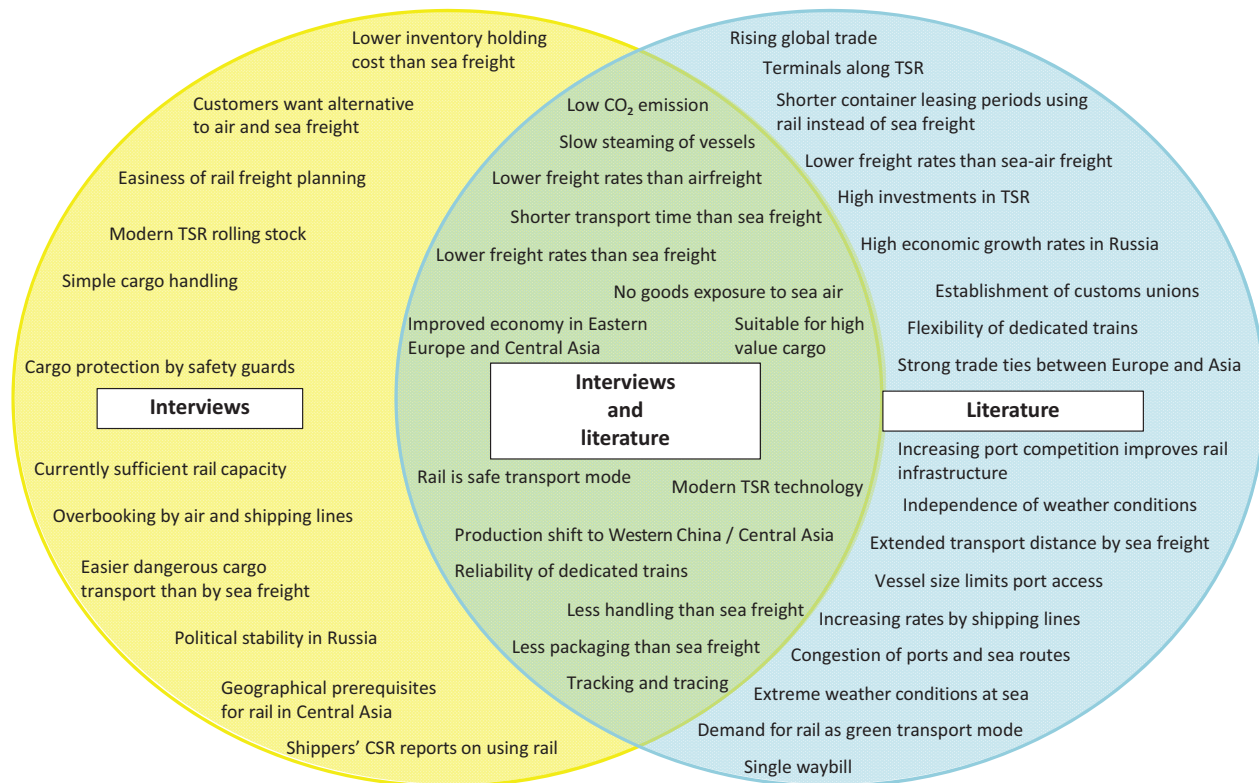

Figure 1 Venn diagram: enablers. *Source: Author.*

train movements over the land bridge. The inventory of enablers and inhibitors was compiled by the research, which was based on a comprehensive review of the relevant literature and was underpinned by primary data collected from 24 semi-structured stakeholder/expert interviews. The outputs of the research study are illustrated in **Fig. 1** (enablers) and **Fig. 2** (inhibitors), with both Venn diagrams illustrating the elements that were identified exclusively from the literature, by stakeholder interviews and common to both sources. Later research adopted similar methods.

The 2013 research identified 45 enablers and 54 inhibitors and these were further classified using PESTLE (political, economic, social, technological, legal, and environmental) analysis and the output is illustrated in **Figs. 3 and 4**. Again, similar methods were adopted in later research.

Eurasia Rail Freight: Development and Current Market Position

The basic idea of using rail freight across Eurasia remains unchanged. Given its characteristics of being faster than sea freight and more economic than airfreight, rail freight fits into a strategic market niche between the two established options of low cost/long lead time (sea freight) and high cost/short lead time (airfreight) (**Fig. 5**). Other alternatives, such as sea-airfreight or intercontinental road freight that might have cost/time ratios comparable to rail freight, are limited with regard to capacity. Rail freight is hence conceptually suitable for cargo that is too time-critical for sea freight (e.g., due to urgency or high capital tied-up), too cost-sensitive for airfreight, and too bulky or heavy for air, sea air, or road freight.

When comparing Eurasian rail freight in 2013 to today, a trend becomes clearly noticeable in terms of increasing transport volume and number of trains (**Figs. 6 and 7**).

The range of services offered by the Eurasia railroad for the years 2013 and 2019 are compared in **Table 1**. The key development in the marketplace is the introduction of a less than full container (LCL) offering.

Table 2 (east-west) and **Table 3** (west-east) compare the variety of goods being shipped by rail along the Eurasia rail bridge for 2013 and 2019.

From this, it can be concluded that the demand for Eurasian rail freight has increased which, in turn, indicates an expansion of the previously introduced market niche. Referring to **Fig. 5**, such expansion comes with a reduction of transport cost and/or transport time and leads to the following hypotheses on the recent development and current state of Eurasian rail freight:

- An increased number of routes and terminals enhances the geographical catchment area of rail freight and thus reduces transport distance to and from terminals;

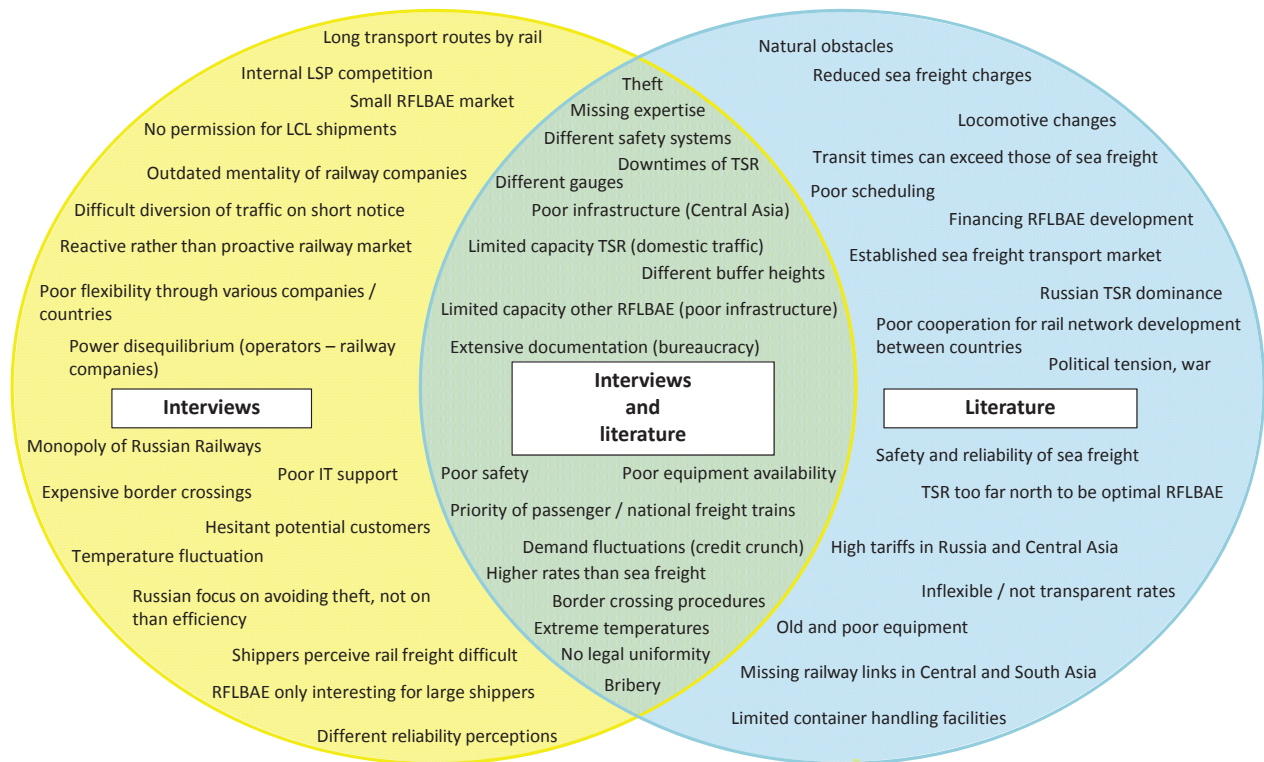

Figure 2 Venn diagram: inhibitors. *Source: Author.*

- An increased number of departures reduces waiting time for individual shipments;
- An increased number of departures reduces cost (e.g., overheads or transshipments); and
- An increased number of routes and departures enhances the importance of intercontinental rail freight for the Eurasian economy and may hence contribute to smoothing processes in order to reduce both cost and time.

The research conducted in 2013 grouped enablers and inhibitors using the PESTLE framework and found the majority of both being technological and economic aspects that are predominantly related to the category's infrastructure, processes, and transport cost. Hence, in the following the recent development of each category is outlined and assessed with regard to its impact on transport cost and time.

Running Trains Across Eurasia

Infrastructure

Fig. 8 shows the current Eurasian railway network and additional connections under construction.

Appendix A provides an overview of the technical characteristics (rail gauges, loading gauges, safety/signaling systems, power source, degree of electrification, and double tracks) of the individual national railway systems of the major Eurasian/Asian rail freight routes. It becomes obvious that the current Eurasian railway network is far from being integrated in terms of track and loading gauge, safety systems, propulsion method, and the degree of track electrification. As a change of these preconditions is extremely unlikely in the near future, infrastructure development predominantly focuses on the improvement and extension of certain (national or regional) networks and neglects the realization of infrastructural uniformity.

In terms of network improvement, tracks in many Central Asian (including Russia) and Eastern European countries have been modernized in order to allow higher speeds, increased weights, and extended lengths of trains. Likewise, many sections have been electrified and equipped with double tracks in order to increase capacity and reduce the number of required locomotive changes. In Central Asia, an increased use of alternative routing options can be witnessed that is related to a broader use (and modernization) of existing infrastructure. While great progress has been made, network modernization has not yet been completed.

Projects to facilitate the extension and further integration of existing networks are in progress, such as the construction of normal gauge routes from China to Turkey (via Central Asia), Pakistan or Singapore (Kunming–Singapore railway), as well as the elongation of the broad gauge network to Vienna, but none have been accomplished to date. In contrast, the number of access points to Eurasian rail freight (and hence the land bridge's geographical catchment area) has already been significantly increased by constructing new terminals or by including existing ones in (new) rail services.

2013	2019
• Consumer electronics (laptops, tablets, computer screens)	• Consumer electronics (laptops, tablets, computer screens, smartphones, television sets, printers, electronic parts) • Machinery and equipment • Industrial goods (robots, high-tech, cooling fans) • Cars (to Central Asia), car parts, and spare parts • Consumer goods, e-commerce, retail, and merchandize (cosmetics, toothpaste, paper, ceramics, luggage, stationery, handicrafts, household appliances) • Garments/high-end fashion • (Industry) minerals • Flowers and trees

Table 3 Eurasia railroad type of goods shipped west to east for 2013 and 2019

2013	2019
• Car parts • Chemicals and hazardous material	• Cars, car parts, and spare parts • Chemicals and hazardous material • Food (cheese, chocolate, olive oil, pasta, wine, baby formula, spirits, beer, milk, meat) • Luxury goods, apparel, cosmetics, garments, and leather goods • Flowers • Pharmaceuticals • Machinery and equipment • Oil, coal, and gas (from Central Asia) • Grain and vegetables (from Central Asia) • Timber

For a detailed overview of current rail freight connections including route and service characteristics, as well as their start and end terminals, refer to [Appendix B](#). Please note that the indicated routes exclusively refer to direct connections. While Chinese terminals rather present immediate transshipment points to their respective hinterland, Europe has a more integrated intermodal rail freight network. In this, terminals that are connected with China via a trunk route collect or distribute containerized cargo via branch lines from start to end terminals (hub and spoke system). Needless to say, this amplifies the number of possible connections to a large extent.

Over recent years, there has been a considerable growth in cargo volumes ([Fig. 6](#)), train departures, and offered connections: from barely a scheduled service in 2011 to about 9000 trains in 2018 ([Fig. 7](#)). While these numbers are still small compared to sea freight, the market state cannot be considered as “infant” anymore, but rather as an established (although small) alternative to the incumbent modes of transport. The growth of volumes is expected to continue over the next years and hit 1 million TEU [Twenty Foot Equivalent Units] (equaling more than 10,000 trains) by 2020. Logically, the majority of trains currently run via the “established” routes, the TSR, or through Kazakhstan, and only a small share via the new connections through Turkey ([Fig. 8](#) and [Appendix B](#)). Shipments through Turkey, however, are likely to quickly gain popularity, especially for shipments between Western China and Southern Europe.

Despite the achieved and forecasted growth, Eurasian rail freight at large scale is still a new transport product. Hence, many shippers and logistics companies are inexperienced and thus insecure when it comes to aspects such as documentation, regulation, and, importantly, simply knowing “the right people” to facilitate and expedite solutions to operational issues. While anyone can send cargo across Eurasia, the picture changes when it comes to operating and steering trains. Whereas in many European countries

open market access applies to industries like logistics and rail transport, competition is impossible in the case of state-owned railways in China, Central Asia, and Russia. Moreover, in China, logistics companies and freight operators that manage international rail freight (block train companies) are required to possess special licensing.

As opposed to the logistical simplicity of maritime transport, running trains across Eurasia comes with an immense increase in complexity that affects shippers and logistics companies at strategic, tactical, and operational level. Strategic and tactical considerations range from understanding demographics via redesigning supply chains (e.g., production and storage facilities) to pursuing the adaptation or even construction of infrastructure and, most importantly, developing a strong pioneer mentality. At operational level, it is mainly technical, geographical, and legal aspects that are key to planning and decision-making.

Reliable information on available services and their departures have improved considerably. This can be seen in the overall market growth, as well as in the increase of involved logistics companies, forwarders, and freight operators that compete for cargo and hence pursue marketing activities and provide solid information. Incoterms are usually like those of sea and airfreight (e.g., EXW [ExWorks], FOB [Free On Board], or DDP [Delivered Duty Paid]). Due to the rising demand, certain services require reservations about 5 days before the train departure.

Environmental and Political Framework Conditions

Bridging Eurasia by rail means exposing both equipment and cargo to a range of challenging circumstances such as:

- Extreme temperatures (ranging from 40 °C in Chinese and Mongolian deserts to −40 °C in Siberian Tundra and Taiga during winter);
- Strongly fluctuating temperatures and related moisture (at yearly, daily, and also regional level);
- Geographical obstacles such as deserts, mountain ranges, earthquake-prone regions, forests, swamps, as well as rivers, lakes, and straits; and
- Unstable political situations.

While the first two put a high demand on running trains (e.g., regarding punctuality) and especially protecting cargo (e.g., food, cosmetics, or electronics), the latter two impact the construction and upkeep of infrastructure, as well as the trust of shippers.

Tracking and tracing of cargo is generally possible, so that shippers can follow their cargo online. With regard to security, containers can be equipped with electronic seals or light sensors to indicate when (and where) a container has been opened. This has immensely reduced the need for employing armed guards. Referring to tracking and tracing as well as equipment for cargo security, it must, however, be considered that many devices work similar to a SIM card in a mobile phone and hence do not necessarily work in each country passed. Integrated tracking and security systems are still to be introduced.

Train Length

As the maximum possible train length differs per country, there is no overall train length for the Eurasian land bridge. As a rule of thumb, however, a train is made up of about 43 railcars (that hold 86 TEU) reflecting the maximum lengths in China and Western Europe (750 m). Countries like Russia that allow much longer trains (up to 1 km) often combine two trains to cross the country and only separate them at the outbound border.

Border Crossings and Gauge Changes

Referring to the previous paragraph on missing infrastructural integration, running trains across Eurasia rather equals an “Olympic torch relay” (Hillman, 2017), where coordination and collaboration are essential to achieve a seamless outcome. Thus, interoperability between the individual network sections is currently ensured by changing equipment like locomotives and railcars at certain points along the route. For example, gauge changes typically take place at (or close to) national borders. While it seems to be best practice to transship liquid or dry bulk cargo with pipe systems, containers are moved by cranes between railcars of different gauge that are lined up side by side. Parallel to the transshipment of cargo that takes at best an hour per container train, the authorities usually manage import and export activities including documentation, and train operators perform quality checks on the rolling stock. Even though the individual changes of equipment only account for a relatively small share of the total transport time, they present a considerable risk of delays (e.g., in case of unavailable equipment for the upcoming section) and consequently require a high degree of asset planning and chain synchronization. In addition, regular waiting times (of many trains) at a certain point along the route are an attractive spot for vandalism or theft. While cargo within a container seems to be generally secured, diesel generators for refrigerated containers are easy targets, which in turn exacerbate the transport of temperature sensitive cargo.

Line Speed Versus Travel Speed

Considering the distances and transit times depicted in Appendix B, one can easily derive the average line speed per connection (28.3 km/h for the example Zhengzhou–Hamburg). Travel speeds are usually higher, ranging from 80 km/h up to 90 km/h or even 120 km/h on modernized sections. What causes relatively low average speeds is considerable waiting times, either within the network of a certain country or at borders between countries. The former is about priorities given to passenger or national freight

trains, extremely dense networks (e.g., in Western Europe, Moscow), or infrastructure sections that need improvement (e.g., in Mongolia, Uzbekistan, Azerbaijan, or Iran) resulting in speeds being down to 250 km per day (as opposed to speeds of more than 1000 km per day in Russia). The latter refers to procedures around borders that are still extremely inefficient. In this, it is not necessarily the pure transshipment of containers, but rather upstream and downstream processes that amplify the borders' characteristics as bottlenecks in the chain. Not only do these circumstances slow down planned travel times, they also present a major reason for delays that can easily amount to 2–6 days. As the previously outlined procedures seem to be alike across the different borders, it is difficult to identify "a route with best practice" in terms of interoperability. What rather impacts the quality of border crossings is the number of trains to be handled. In this, serving few trains results in smooth processes while many trains cause bottlenecks and delays. Hence, referring to Appendix B it becomes obvious that the border crossing Terespol–Brest at the Polish–Belarusian border is one of the weakest links of the entire network and shippers already seek to find alternatives. Other border crossings, however (e.g., between China and Kazakhstan respectively with Russia), already show similar tendencies, which is due to the overall increase in freight volume. Fig. 5 clearly shows that unpunctuality negatively impacts lead time and is thus a major threat for the competitiveness of Eurasian rail freight.

Policies and Legislation

Obviously, rail freight across Eurasia remains complex, which is due to the number of countries crossed, and thus different political, legislative, and organizational conditions are to be considered. In particular, China is to be regarded as complicated as each province has its own regulations that may exacerbate processes, especially with "nonstandardized" cargo such as dangerous goods. Nevertheless, several former pitfalls, such as slow and nonstandardized customs clearance, arbitrary procedures, as well as extensive documentation (and hence many opportunities for bribery) due to missing legal uniformity have been eased considerably by the creation of customs unions such as the EU or the Eurasian Economic Union (EAEU) that was founded by Belarus, Kazakhstan, and Russia in 2011 and extended to Armenia and Kyrgyzstan in 2014. While rail freight still requires more documentation compared to sea freight, procedures have been simplified and standardized (e.g., customs surveillance code 9610, the EAEU customs code in 2018, or the definition of general terms and conditions by the international rail transport committee in 2019) so that shippers and logistics companies do not have to arrange documentation with each country crossed any more. Together with the buildup of a solid base of experience, this has reduced formalities around borders to about 4 h. Hence, customs clearance and documentation with border crossings do not present a serious barrier to intercontinental rail freight any more. A further legal factor that has considerably contributed to growing volumes, broadening the base of potential (medium to small) shippers and realizing more stable demand patterns, is the possibility to send single containers or even LCL shipments, as opposed to a dedicated block train as in the past.

Cost and Subsidies

Obviously, a major modal choice criterion is cost. Cost for running trains (across Eurasia) among others comprises elements such as:

- Equipment (wagon and container rent);
- Infrastructure (access charges, traction, energy);
- Processes and procedures (customs, transshipment, security guards, border crossings, formerly bribery, change of rolling stock to due gauge change);
- Transport chain (pre- and post-haulage, terminal handling fees, storage fees at terminals, repositioning of empty wagons and containers); and
- Capital cost related to the shipped goods.

In 2013, transport rates were described as high, nontransparent and characterized by a high dependency on Russia and Central Asia. Comparing rates between 2013 and today show that for sea and airfreight there has been little change, while rail freight rates have been reduced by about one-third (Table 4).

Table 5 provides an example for current LCL freight rates. As LCL shipments (refer to Table 1) have only become possible in recent years, a comparison is obviously impossible.

Obviously, as rates are highly dependent on the origin and destination of the shipment, as well as on the characteristics of the route, the earlier values should serve as an indication of price ranges in comparison to other modes of transport. Both, lower and

Table 4 Freight rates 2013 and 2019

<i>Charge rates per container</i>	<i>2013</i>	<i>2019</i>
Sea freight (east-west)	\$2,000–\$5,200	\$2,000–\$6,200
Rail freight (east-west)	\$5,500–\$6,600	\$3,500–\$4,500
Airfreight (east-west)	\$18,000–\$24,000	\$18,000–\$28,000

Source: Adapted from Vinokurov et al. (2018).

Table 5 Freight rates 2013 and 2019

LCL freight rate	2019
Sea freight (east-west)	\$40 per m ³ or 1,000 kg
Rail freight (east-west)	\$115 per m ³ or 500 kg

Source: Adapted from Desormeaux (2019).

higher (rail freight) rates are possible. What is important for shippers in practice is a comparison of rates at individual route level and under consideration of needs and demands in the supply chain.

When comparing rates, it is moreover important to consider that rail freight across Eurasia is still heavily subsidized. The real cost for sending a container across Eurasia by rail is estimated at about \$9,000–\$10,000 (Wallis, 2018). Referring to the rates as indicated in Table 4, this results in subsidies of about \$5000 per container (Liang, 2018). Hence, in order to maintain current prices in the future, significant efficiency improvements are necessary after the ceasing of subsidies.

While the determination of rail freight rates is generally complex and hence prone to nontransparency (including charges for access, capacity, traction energy [electricity or diesel], as well as stations or depots), it is considerably exacerbated when it comes to the numerous activities related to rail transport across Eurasia. Research (Jakobowski et al., 2018) roughly divides revenues for terminal-to-terminal container transport between forwarding company (5%), intermodal operator (5%), and carrier as well as infrastructure provider (90%). However, a detailed distribution of costs incurred along the route (e.g., using a pie chart) could not be found in any of the literature considered and seems (currently) impossible. For that reason, it is unlikely that the transparency of freight rates has improved over the last years or that it will improve any time soon. At least with regard to the publishing of rates, as well as the debating of subsidies, in the literature, transparency can be considered as slightly improved.

Political and Macroeconomic Conditions

The dependency on Russia and Central Asia persists (refer to Fig. 8 and Appendix A). However, the use of various routes and construction of new connections make shippers less dependent on individual (less favorable) sections.

A macroeconomic phenomenon that characterizes trade between Asia and Europe is the imbalance of trade and hence cargo volumes. As is apparent in Figs. 6 and 7, there is a considerable imbalance of trains and shipped TEU in favor of east-west flows (more than two-thirds) compared to west-east flows (less than one-third). Certain references go a step beyond and also consider the loading degree of trains (and more importantly of containers on trains) showing an even more extreme imbalance, with loading

Figure 8 Eurasian railway network. Source: Rodemann et al. (2018).

factors of westbound trains being about 90% (new Chinese policies do not allow shipping empty containers to Europe by rail) compared to 20% for eastbound trains (it does happen that an empty pallet is put into a container to change its status to “loaded” [Szakonyi, 2018]). This represents a huge financial burden with regard to freight rates as well as cost for repositioning of empty containers and rolling stock, especially in the light of intercontinental rail freight being a relatively young product seeking competitiveness without subsidies.

Summary

The earlier description of the current state of Eurasian rail freight is now summarized with regard to the impact on transport cost and time in order to assess whether the former strategic niche of intercontinental rail freight is expanding or not. This is done with the help of the previously introduced hypotheses (Table 6). Subsequently, the mitigation strategies (Table 7) and inhibitors (Table 8) identified in 2013 are reviewed with regard to their continued presence or status in 2019, in order to answer the two key questions of this paper. Finally, a set of newly emerged enablers is presented (Table 9).

As mentioned earlier, the 2013 research collected possible strategies to mitigate inhibitors (and turn them into strengths). Table 7 lists these strategies and indicates the individual extent of realization in 2019. The order of the listed mitigation strategies reflects the frequency of findings in 2013 (starting with the most frequent strategy and descending subsequently).

Corresponding to the realization of mitigation strategies presented in Table 7, Table 8 shows the applicability (in 2019) of those inhibitors identified in 2013.

Based on the previous paragraph, Table 9 lists new enablers and inhibitors that have emerged over the recent years and will influence the future development and growth of the land bridge. To be in line with the 2013 research, Table 9 categorizes the enablers and inhibitors based on the PESTLE framework.

From the earlier, one can draw the conclusion that the strategic market niche of Eurasian rail freight is extending. In a virtuous circle, the increase of services has enhanced the number of shippers, which, in turn, has caused further connections to emerge. This

Table 6 Time and cost analysis

<i>Hypothesis</i>	<i>Applies to a</i>	<i>Reason</i>	<i>Impact on transport cost</i>	<i>Impact on transport time</i>	<i>Future development potential</i>
An increased number of routes and terminals enhance the geographical catchment area of rail freight and thus reduce transport distance to and from terminals.	High extent	• More terminals are linked to the land bridge which results in more routes • The network is extended which allows more route options	• Shorter total transport distance reduces cost • Shorter pre- and post-haulages reduce cost	• More routes link more cities which reduces the total transport distance for individual shippers/consignees to and from the closest terminal	• Additional terminals and routes • Further extension and integration of the railway network
An increased number of departures reduce waiting time for individual shipments.	High extent	• Especially highly frequented routes allow daily departures and hence reduce lead times for individual shipment	• No direct impact on transport cost • Less waiting time, however, reduces the capital tied-up	• No direct impact on transport time • Higher departure frequencies reduce total (average) lead time for individual shipments	• Further increase of departure frequency
An increased number of departures reduce cost (e.g., overhead or transshipments).	Low extent	• This is generally possible • Current rates, however, are to a huge extent achieved through subsidies	• Reduction of indirect cost per shipment • Reduction in capital tied-up	• See earlier line	• Volumes must considerably increase in order to generate sufficient economies of scale • Subsidies are currently more decisive than cost
An increased number of routes and departures enhance the importance of intercontinental rail freight for the Eurasian economy and may hence contribute to smoothing processes in order to reduce both cost and time.	High extent	• Border processes have been smoothed • Documentation has been eased • LCL shipments have been made possible	• Less administrative cost • Less capital tied-up	• Less waiting times • Less delays	• Further smoothing of processes • Standardization and harmonization of regulations • Eased market access

Table 7 Possible strategies to mitigate inhibitors

<i>Strategy</i>	<i>Main influencer</i>	<i>Extent realization until 2019</i>	<i>Evidence</i>
Joint infrastructure development (track modernization and new lines)	G	High	Modernization of infrastructure in Central Asian countries (e.g., Kazakhstan)
Simplification of border procedures/single-way bill	G	High	New lines from China to Turkey, Pakistan, and Singapore
IT infrastructure for real-time information (tracking and tracing/GPS use)	L&T	Medium	Customs/border crossing procedures have been eased (electronic processes)
Marketing	L&T	High	Demanded and already in use, but functionality along the entire route to be improved
Enhancing value propositions	L&T	Low	Major logistics companies offer Eurasian rail freight
Introduction of competitive rates	RC	High	BRI (Belt and Road Initiative) as a tag
Information sharing	AP	Medium	No evidence found
Extension of wide gauge network	G	Low	Subsidies have considerably reduced rates
New T (container handling and gauge changes)	G	Medium	Availability of information on services is improving. Still little information sharing between individual parties and still no transparency regarding cost and rates
Improving traffic management	RC	Low	No evidence found
Using equipment with adjustable bogies	RC	Low	Route to Vienna not yet finished
Discussion with authorities (improving/reducing customs procedures)	L&T	High	Several new services have been started and built/linked new terminal to the network
Tariff harmonization	G	Medium	No evidence found
System integration and collaboration to achieve standardized interoperability (technical, commercial, administrative)	G	High	Still considerable bottlenecks
Introduction of heatable containers and insulating packaging	S	High	No evidence found
China as major money supplier	G	High	Customs/border crossing procedures have been eased (electronic processes)
Speeding up loading and gauge changes	T	Medium	Rates have been reduced through subsidies
Improving economic relations between Russia and China	G	Medium	Subsidies still vary considerably between Chinese provinces
Creating/enlarging customs unions	G	High	Customs/border crossing procedures have been eased (electronic processes)
Running test trains	S	High	Refer containers are commonly used
Normal gauge line across Central Asia	G	High	China is to a great extent financing national and international infrastructure projects
Electrification and double tracking	G	High	Transshipment process lasts about an hour per train
Use of passenger locomotives	RC	Low	Up- and downstream processes still present bottlenecks
Rate standardization/single through rates	RC	Low	Increased number of services
Increasing global container trade	S	Medium	Still low number compared to China–Europe
Transit in 7 days program	RC	Medium	European Union (EU) and Eurasian Economic Union (EAEU)
China–Europe–Northeast America program	RC	Low	New routes and services are likely to use test trains (e.g., to Madrid or London)
Using dedicated trains	S	High	Normal gauge route built between China and Turkey
Minimizing empty wagons/containers	L&T	Low	Many tracks in Central Asia (e.g., Kazakhstan) have been modernized
Joint ventures	RC	Low	No evidence found
New/modernization of locomotives and wagons	RC	Medium	Rates are highly dependent on subsidies of Chinese provinces and hence differ a lot
Hybrid propulsion	RC	Low	Considerable growth of Eurasian rail freight
Speeding up trains	RC	Medium	Global trade is reaching saturation phase
Separation of freight and passenger trains	RC	Low	China's economic growth is slowing down
Reducing amount of network operators	G	Low	Trains in Russia achieve speeds of +1,000 km per day
Developing industrial production along RFLBAE	G	High	Bottlenecks at borders remain or increase due to increased traffic
			No evidence found
			Several Chinese provinces use dedicated trains to Russia and Europe
			There is still many empty containers / containers “loaded” with one pallet
			The service is still provided by individual train companies
			In China there is little collaboration between competing provinces
			Central Asian countries (e.g., Kazakhstan) have modernized their rolling stock
			No evidence found
			Modernization of certain sections allows higher speeds
			Lead time is still low due to bottlenecks and increased traffic
			No evidence found
			The service is still provided by individual train companies
			Chinese (mega) cities such as Yiwu, Wuhan, Chengdu, and Chongqing
			Logistics parks in Kazakhstan, Belarus, and Ukraine

AP, all parties; G, government; L&T, logistics and transport; RC, railway companies; S, suppliers; T, terminals.

Table 8 Eurasia inhibitors identified by the 2013 Cranfield study

<i>Pestle category</i>	<i>2013</i>	<i>2019</i>
Political	Political tension and war Poor cooperation for development	Political instability in Eastern Europe, Central Asia, Iran, and Turkey remains Despite heavy involvement of China and also Belgium and Germany, there is still little cooperation between countries
Economical	Russian TSR dominance Question of financing development Higher rates than sea freight Monopoly of Russian Railways Reactive, not proactive railway market Small RFLBAE (rail freight land bridge between Asia and Europe) market Outdated mentality of railway companies Russian focus on avoiding theft, not efficiency	Reduced due to alternative routes High involvement of China Subsidies have reduced the difference between rail and sea freight rates Reduced due to alternative routes No evidence for change Considerable growth in terms of cargo types, volume, trains, and connections
	Power disequilibrium (operators vs. railway companies) Hesitant potential customers RFLBAE currently only interesting for large shippers	No evidence for change Growth of market has increased the number of shippers Introduction of single wagon and LCL shipments also makes rail freight interesting for smaller shippers
	Susceptible to demand fluctuation (credit crunch) Rail freight is perceived difficult by shippers	Volume growth has made market less susceptible to demand fluctuation Rail freight is still complex, but an increase in market size and players also increases the experience of participants (including shippers)
Technological	Internal LSP (logistics service provider) competition Different reliability perceptions TSR too far North to be optimal route Establish sea freight market Inflexible and not transparent rates High tariffs in Russia and Central Asia Reduced sea freight charges Expensive border crossings	No evidence found (in theory it is still existing) No evidence for change No change; however, there is alternative routes No evidence for change No evidence for change No evidence for change No evidence for change Procedures have been standardized and simplified
	Different gauges Different safety systems Limited capacity on other RFLBAE (poor infrastructure)	No evidence for change No evidence for change The establishment of new infrastructure has increased the capacity; the increase in volumes, however, also requires high capacity
	Limited capacity on TSR (domestic traffic)	No evidence for change; a huge share of trains takes the TSR (at least for a certain part of the trip)
	Different buffer heights Priority of passenger and national freight trains Poor infrastructure in Central Asia	No evidence for change No evidence for change Investments in infrastructure have improved the network (especially in Central Asia)
	Poor IT support	IT support has improved; a comprehensive tracking and tracing along the entire route remains difficult
	Poor flexibility through various companies and countries involved Difficult traffic diversion on short notice Limited container handling facilities Old and poor equipment Transit times exceed those of sea freight	No evidence for change New routes are expected to increase the flexibility for shippers Heavy investments in infrastructure have increased the number of terminals Heavy investments have modernized or renewed equipment Rail freight is generally faster than sea freight; there can significant delays with rail freight
	Safety and reliability of sea freight Locomotive changes	No evidence for change No evidence for change; the uniform electrification of several sections, however, reduces the number of necessary locomotive changes
	Missing railway links in Central and South Asia	New links and connections between existing infrastructure have been established
	Poor scheduling Poor safety	Scheduling of border crossings and in dense networks remains a weak point There is less evidence and less armed guards; border crossings remain dangerous especially in terms of diesel and generator theft
	Downtimes of TSR Equipment availability	No evidence for change Sufficient equipment is available; short-term unavailability of equipment exists with transfer points (e.g., locomotive changes and border crossings)

(Continued)

Table 8 Eurasia inhibitors identified by the 2013 Cranfield study (*cont.*)

<i>Pestle category</i>	<i>2013</i>	<i>2019</i>
Social	Cargo and equipment theft	There is less evidence and less armed guards; border crossings remain dangerous especially in terms of diesel and generator theft
	Bribery	The standardization of procedures has reduced the possibility of bribery; it, however, still exists
	Missing expertise	The growth of market has contributed to the increase of expertise with various parties
Legal	No permission for LCL shipments	LCL shipments are now possible
	Extensive documentation	Documentation has been standardized and simplified
	Extensive border crossing procedures	Procedures have been standardized and simplified
	No legal uniformity	Still no complete legal uniformity, but EU and EAEU have standardized regulations within their territories
Environmental	Extreme temperatures	No evidence for change; the use of reefer containers is a possible mitigation strategy
	Long transport routes by rail	No evidence for change
	Natural obstacles	No evidence for change
	Temperature fluctuation	No evidence for change; the use of reefer containers is a possible mitigation strategy

Table 9 New enablers and inhibitors to Eurasian rail freight in 2019

<i>PESTLE category</i>	<i>2019 enablers</i>	<i>2019 inhibitors</i>
Political	- Subsidies by Chinese government - More and more countries are involved in BRI and are interested in investing	No new political inhibitors identified
Economical	Enhanced flexibility in the supply chain through competition between newly established routes	- Cannibalism through competition between terminals - Cannibalism through competition between routes
Social	- New growth potential, for example, through increased e-commerce - No new social enablers identified	- Imbalance of trade volume (east-west vs. west-east) - No new social inhibitors identified
Technological	- Improved tracking and tracing - Block chain and smart contracts	No new technological inhibitors identified
Legal	Implementation of new customs procedures	No new legal inhibitors identified
Environmental	Increased environmental awareness and low emissions of rail freight compared to airfreight	No new environmental inhibitors identified

growth of the market is mutually related to significant enhancements in terms of processes, procedures, and legal framework conditions (including subsidies for lower rates) that created more attractive circumstances for shippers and contributed to the earlier outlined reduction of transport cost and time.

Future Outlook

Having evaluated the current state of Eurasian rail freight, the focus is now on the future of the Eurasian land bridge between China and Europe, focusing on the original inhibitors that still need to be addressed (**Table 8**), together with recent enablers and inhibitors that will have a positive impact on the future development of the land bridge (**Table 9**). Finally, this paper focuses on the current plans that are being implemented and the future opportunities that are being considered that will influence the development of the Eurasian land bridge.

The future development and growth of the Eurasia railroad will be dependent on tackling the following issues:

- The need to build a financially sustainable railroad;
- Managing the future expectations associated with westward migration;
- Mitigating risk and achieving resilience;
- Solving the trade imbalance between freight moving from China to Europe compared to that from Europe to China;
- Managing internal demand for freight terminals;
- Future economic growth; and
- Extending the geographic reach of the railroad.

Figure 9 Scenario analysis. *Source: Author.*

The recent success of the railroad has been generated by the Chinese state investment in new infrastructure and subsidized freight rates. There are no guarantees that this state support will continue into the future, and the warning signs are already being signaled by the Chinese state that freight subsidies will be reduced and possibly phased out entirely in the near future. China wants to see additional investment in the railroad from their rail partners along the various routes and is not prepared to fund the project alone and let other states have a free ride on the back of Chinese investment.

Over recent years there has been a significant movement of people and businesses migrating westward away from the Chinese coastal cities inland to the central regions. This has resulted in greater demand for connectivity to facilitate the movement of people, resources, and goods for exporting to international markets. Migration has been one of the contributing factors that has stimulated the demand for, and interest in, improved and new investment in Eurasia rail links.

Traditionally, high value goods such as electronics, computers, and mobile phones have been exported to overseas markets from China by air. However, as manufacturing costs have decreased, airfreight costs are now becoming a greater percentage of total costs. Alternative transport modes such as rail freight are now being considered as an alternative to airfreight and the Eurasia railroad is now well placed to take advantage of this modal shift. This is because transit times from China to Europe are between 2 and 3 weeks, which is half the time of sea freight, and are also considerably cost-effective when compared to airfreight charges. A further reduction of rail freight lead time would obviously improve the competitive position of the Eurasia railroad compared to airfreight. **Fig. 9** presents a lead-time scenario analysis at different average line speeds using the previous example Zhengzhou–Hamburg. What is striking is that an increase of the average line speed to the (approximate) regular travel speed of freight trains would reduce the current lead time by about 60%. This could be achieved by a combination of advanced scheduling and comparably small improvements of certain infrastructure sections to remove current bottlenecks. The potential for further lead-time reduction exists with high-speed rail freight. However, this would require the extremely costly upgrade of practically the entire railway network and, moreover, the development and acquisition of new rolling stock.

The enhancement of the Eurasia railroad links also provides China with an alternative conduit for international trade, thus reducing strategic risk and enhancing resilience, just in case their traditional sea-lanes are disrupted in the future.

For the railroad to be financially sustainable, the trade imbalance needs to be addressed, as freight movements from China to Europe considerably outweigh the reverse flow. Empty running/low utilization is a significant issue for freight transport, whichever transport mode your business operates.

The prolific growth in the number of Chinese cities wishing to participate in the phenomenon of the Chinese railroad renaissance is clear to see by the increase in new routes. However, this growth has been supported and encouraged by government incentives and policy. Also, the international prestige that the rail links provide to a city and its hinterland is also a factor. The big issue that needs to be considered for the future development of these railheads is whether there is sufficient demand to support all of them. If not, the future could see existing cities and new entrants moving into the marketplace and cutting freight charges to attract customers, resulting in a “beggar my neighbor” culture, which may well benefit shippers in the short term, but could have a detrimental impact on the mid- to long-term future development of the railroad.

Economic growth will be a considerable factor that will determine the growth in demand for rail freight services along the Eurasia rail network, not only the demand for Chinese exports to the west, but also the demand for western imports into China. China’s economic growth is also essential in order to continue the capital investment in the BRI infrastructure projects if the Eurasia railroad is to achieve its aim and objectives. The impact of future trade deals will also influence the level of goods shipped via the Eurasia railroad.

Extending the geographical reach of the Eurasia railroad to link islands such as Japan, Taiwan, and the Philippines (by vessel to China), as well as mainland countries in Southeast Asia and the Korean peninsula, provides additional services for shippers. Furthermore, it enables railheads such as Chongqing to operate as a hub-and-spoke node or an aggregator. However, it requires additional investment in railway infrastructure to achieve the enhanced network.

To stabilize and further improve its position, Eurasian rail freight literally still has a long way to go. Having become more economically interesting, it is now important to provide sufficient infrastructural capacity, quality, and transport chain resilience to remove bottlenecks and to guarantee smooth and reliable operations. Moreover, in the medium to long run, further cost reductions will be inevitable in order to become independent of subsidies and ensure financial stability. Eventually, however, the decisive factors will be macroeconomic conditions that generate future growth, as well as balanced cargo flows between Asia and Europe and an appropriate use of terminals to realize (but not jeopardize) a comprehensive catchment area of the railroad across Eurasia.

Acknowledgment

We would like to sincerely thank Cranfield University, the sponsor of the initial research, for its financial support and the contribution of contacts. In addition, we owe special thanks to all interviewees for the engaging conversations and the provision of valuable information. We are extremely grateful to Fred Wan for his informative support, the validation of information, and most importantly his enthusiasm on the research. Last but not least, our gratitude goes out to Frans de Jong for his support with the map.

Introduction

As international trade and cargo demands are growing, existing infrastructure capacities will be stretched to their limits, leading to increasing congestion, safety concerns, environmental issues, and diminishing reliability of services. Given the major challenge of decarbonizing the freight transport sector in the face of climate change, existing instruments will not suffice to sustainably deal with the expanding market (European Commission, 2011). By 2050, freight is projected to account for 60% of total transport greenhouse gas emissions, up from 42% in 2010 (OECD, 2015). Therefore, the European Commission aims to move 30% of road freight transport to more sustainable modes such as rail and inland waterways by 2030, increasing to 50% by 2050. These ambitions will require innovative solutions for a more seamless and cost-effective integration of the various transport modes. On the way to more environmental and socioeconomic sustainability, the usage of the existing assets constitutes a major challenge for the transport sector. Here, the core issue is the current user preferences and mode selection in favor of road transport. Given the dense road network, road transport can offer door-to-door transport solutions from almost anywhere to everywhere on the continent. Such unimodal door-to-transport chains are much less likely to be available via rail or inland waterway transport. Instead, they often need to be combined with other modes to form one integrated transport chain. Such transportation of goods by at least two differing modes is defined as multimodal transport. Further defining concepts exist: Intermodal transport is the movement of goods (which remain in the same vehicle or loading unit) by numerous modes of transport without the goods themselves being handled when switching modes (Eurostat, 2003). Combined transport applies more emphasis on reducing the road delivery element within the initial/final leg, so that the main leg by barge or train is as long as possible in order to reap economies of scale. Comodality focuses on balancing different modes and their combinations for optimum overall resource efficiency (Eurostat, 2003). Lastly, synchronomodality emphasizes the structured and synchronized combination of modes, including real time (re-) evaluations of routes and mode selections during transport (Steadie Seifi et al., 2014). The chapter firstly describes intermodal transport, its costs and evolution in the following sections. Secondly, the concept of synchronomodal transport is addressed in section, “Synchronomodal Transport” which extends the idea of intermodal transport by enabling real-time re-routing of goods along alternative routes in response to disruptions and/or shippers’ requirements. Thirdly, digitalization and data sharing are briefly discussed in section, “Digitalization and Data Sharing” followed by concluding remarks in section, “Conclusions.”

Intermodal Transport—Its Costs and Evolution

A distinctive characteristic of intermodal transport is the use of an intermodal loading unit (ILU). The success of intermodality depends upon the more general adoption of standards that has facilitated globalization, namely through the global use of containers. In 1961, the International Standards Organization (ISO) reached an agreement to set standard sizes of containers to 20-foot (1 TEU or Twenty-foot Equivalent Unit) and 40-foot (2 TEU) lengths. The introduction of containers contributed to lowering freight charges by improving port handling efficiency, but the real outcome of containerization was a boost in trade flows, with major effects that are even noticed by the average person. Every day at every major port, thousands of containers arrive and depart to carry goods that we are depending on. Containers can be moved seamlessly between ships, inland waterway vessels, rail wagons, and trucks through a system of intermodality. In order to establish a complete intermodal freight transport chain, a broader perspective of the logistical chain is considered: not just that the containers need to be standardized, but also the container ships, intermodal terminals,

trucks, and trains need to be adapted to carry the same container, to get it into the hinterland. The major disadvantage of the use of loading units is, however, the need to transport empty or half-empty loading units to satisfy the demand. As a consequence of imbalanced trade flows, empty container repositioning is common practice.

Intermodal transport systems can include a variety of transport modes like shortsea, inland waterway, rail, and air transport. Road transport is commonly used for the pre- and post-haulage, as its extensive infrastructure network enables it to access many locations. Given the growing volumes of maritime containers transhipped, the seaports represent an ideal starting point to stimulate intermodal transport. Establishing intermodal connections not only enables an extension of the hinterland potential of seaports but also contributes to improving the efficiency of the transport system. Intermodal terminals are the critical nodes that allow transhipments between different transport modes. For the transhipment of containers in these intermodal terminals, dedicated infrastructure is required.

In intermodal transport, different logistics chain configurations may involve different types of actors, or actors of the same type playing different roles (Vrenken et al., 2005). Shippers initiate the movement of cargo between locations directly or by means of contracts on their behalf. Intermodal transport services can be optimized by freight forwarders on behalf of shippers. Ocean shipping lines, can also be involved in the hinterland container shipment segment. On the supply side, we find: terminal, rail, inland navigation, shortsea and road transport operators. Operational organization places terminal operators at the core of the intermodal transport chain because of their role in transhipping ILUs between the main haul and drayage. Transport operators handle the movement of the loading units between terminals via rail, inland waterway or sea routes respectively, and road transport operators arrange the local transportation of cargo from origin and destinations. Offering door-to-door or terminal-to-terminal transport, intermodal transport operators procure transport and transhipment services. In addition to these purely commercial market players, the public sector can also be included on the supply side of intermodal transport. Infrastructure managers, port authorities, regional and national public authorities, and international institutions contribute to making the best possible use of infrastructure and provide an environment to encourage intermodal initiatives.

Fig. 1 represents an intermodal and a road-only cost function. For a port-to-door intermodal transport chain, the function shows the total intermodal transport costs, relative to distance, between a port and a final destination. Post-haulage requires an interchange from road transport to another transport mode in an intermodal terminal. From Fig. 1, it is possible to derive the importance of transhipments in an intermodal transport chain.

At the port, intermodal transport has larger handling costs compared to unimodal road transport. This is due to the operations needed for the transhipment of containers on barges or trains. The advantage of intermodal transport lies in the smaller variable costs during main haulage, as a result of the scale economies that are obtained by the large capacities that can be transported by a single movement. Scale economies, gained by the main haulage leg of an intermodal transport chain, can further be increased by the introduction of larger vessels or longer trains. As the variable costs of barge or rail transport is lower compared to road-only transport, the longer distances covered by the intermodal leg will make intermodal transport more efficient than road-only transport. At the end of the chain, this advantage is partly compensated by the extra handling cost that has to be paid for the terminal handling.

Once the different cost components are known, it is possible to make comparisons between intermodal and unimodal road transport. This relationship enables us to understand which transport alternative is costlier in a given situation based on the concept

Figure 1 Intermodal cost function.

Figure 2 Evolution of transport performance in EU-28 between 1998 and 2016. Source: Eurostat (2003)

of break-even analysis. Fig. 1 shows that unimodal road transport performs better compared to intermodal transport for short distances. When a certain distance is reached, the costs of road and intermodal transport are equal. This is called the break-even distance. Above the critical distance point, intermodal transport costs are lower than those of unimodal road transport. The break-even distance is a theoretical concept, as in practice the transport costs are influenced by factors such as capacity utilization, the presence or lack of a full backhaul, etc., and the fact that actual transport distances can be impacted by detours. Other cost factors such as the empty container depot functioning as an intermodal terminal and the effects of congestion also have to be considered in calculating the break-even distances. The actual break-even distance will in any case depend on local market conditions.

Intermodal transport is supported and facilitated by the European Commission as well as by national and regional governments. For port authorities a modal shift can increase their accessibility—by decreasing congestion and extending or creating hinterlands (van Klink and van den Berg, 1998) and, therefore, increase their competitiveness (Vermeiren, 2013). Also, shippers can benefit from a modal shift if the new transport chain meets their preferences (cost, quality, reliability, security, etc.) more than the previous chain. Yet, we see that modal split has remained more or less constant over the last two decades in Europe (Fig. 2).

Synchromodal Transport

Intermodal transport has been seen as a solution to accommodate the shift from road to rail and inland waterways. However, incorporating all possible actors, modes, and trajectories into functioning decision support models for intermodal transport is challenging. The available data is limited and its static nature poses problems. Furthermore, it is perceived as slow, inflexible, and limited in its application from the user perspective of actors such as shippers and logistics service providers (Meers et al., 2017). This also explains the evolution in Fig. 2 in which the modal shift to inland waterways and railways has been modest at best. The target of achieving a modal shift as set out in the introduction is, therefore, still a challenge to attain. Here, the concept of synchromodal transport extends the idea of intermodal transport by enabling real-time re-routing of goods along alternative routes in response to disruptions and/or shipper requirements (Ambra et al., 2019a). It therefore differs from intermodal transport, where services are defined long in advance leading to a static service with low flexibility, and where disturbances and delays easily lead to loss of time or money. Furthermore, the intermodal setting is too inflexible to accommodate newly arriving orders in time. Within the synchromodal approach, routing, and modal choices are made as late as possible to account in real-time for operational and infrastructural developments (Reis, 2015; Tavasszy et al., 2017). Such dynamic re-routing and re-scheduling make it more competitive. This way, synchromodal systems may outperform intermodal transport in terms of reliability and flexibility, and lead to a better integration of different transport modes. Synchromodality is also seen as a solution to counteracting congestion problems and environmental concerns raised by the ever-increasing cargo demands. The concept has even become a component in the European Technology Platform called Alliance for Logistics Innovation through collaboration in Europe (ETP-ALICE) which develops research and innovation agendas for action on supply chain management and logistics at EU and national levels (Fig. 3).

To implement synchromodality, bookings should be made mode-free by shippers. This type of a-modal booking would allow logistics services providers (LSPs) to plan and combine orders more flexibly by making use of various modes, while adhering to customers' requirements. Next to enabling a-modal booking, synchromodal transport requires three further system changes: (1) a shift in approach and thinking from "predict and prepare" to "sense and respond," (2) the creation of standardized cooperation schemes, and (3) a governance system leading to improved operational alignment of the various modes (Tavasszy et al., 2017).

In the synchromodal setting, three aspects of freight transport require synchronization (Ambra et al., 2019b). These are (1) loading units, (2) assets, and (3) infrastructure, with each aspect addressing problems at a different level.

Figure 3 ETP-ALICE roadmap toward zero emissions.

Increasing the Capacity of Loading Units

At the basis of synchromodal transport stands the loading unit. Loading units such as intermodal freight containers are widely standardized to allow for easy handling and stacking at transport hubs and their capacity is usually indicated in TEUs. To achieve a higher fill rate of containers, the lower parcel and pallet levels of a loading unit should be accounted for via modularization, advanced encapsulation processes, and multifunctional load units (Sallez et al., 2015; Tran-Dang et al., 2017), leading to transparency and efficiency across levels. To maximize capacity utilization and revenue, smart containers supported by cloud-computing can achieve better grouping strategies in real time with less empty containers. This way, revenue management of the overall supply chain (Van Riessen et al., 2017) and of individual TEUs should be intertwined. Lastly, sensors and smart tags allow for the tracking of various orders enclosed in a container. Such visibility and location intelligence are paramount for the creation of a unified system that can reliably identify overlapping flows. Such inefficiencies could be assessed and visualized by the synchromodal system, to be then more efficiently bundled at the level of boxes, pallets, and containers (TEUs).

Synchronization of Assets

Another aspect to be synchronized is the asset such as barges, trains, and trucks that move between hubs and delivery locations. In addition, there are also cranes, tugs, and reach stackers which operate in the ports and terminals. Just like containers, these moving assets vary in terms of their size, geographical scale, and infrastructure they follow. Here, synchronization encompasses the optimization of train and barge schedules, the allocation of loading units to modes, and the handling of disruptions and their consequent cost impact (Ambra et al., 2019a; Behdani et al., 2016; Nabais et al., 2015). Nevertheless, intermodal and synchromodal applications concern mainly longer hauls; at the European interregional scale, for instance, while detailed local trucking tends to be detached from the overall solutions. Thus, the main European hubs and corridors should interact with local distributors to create mass for barges and trains, while trucks support synchromodal services by carrying out last-mile deliveries. Merging these two would offer more reliable door-to-door synchromodal coverage where, through integrated planning of modes, fill rates of all transport means can be increased once trucking companies and rail/barge operators optimize their schedules and routings together. Reinforced usage of assets is very important, yet it requires standardized coordination protocols to ease bundling or transitioning, if one intends to preempt closed collaboration contracts that would exclude some service providers.

Infrastructure and Networks

A network in freight models is made up of nodes as well as arcs connecting these nodes. In the case of the freight network, the nodes or hubs are ports, warehouses, and terminals, which are linked by arcs such as roads, rail, and inland waterways. At hubs, the

challenge arises to integrate and align intra-terminal operations with those of logistics service providers and road-inland waterway-rail network developments. This is facilitated by a combination of two types of algorithms: Route prediction algorithms, which are integral to the calculation of the estimated time of arrival and cargo peak prediction algorithms at hubs (Nabais et al., 2015). The coordination of internal-hub movements with external movement outside of the hubs can be facilitated by RFID, Bluetooth, and WIFI structures employed by manufacturers and terminal operators for higher visibility, and other “smart” object solutions for longer distances by means of GPS-enabled devices. For more resilient supply chain structures, synchromodal solutions should be able to react both to external events such as rail strikes or lower water levels, and to factory production disruptions. Besides these, opportunities such as vacant capacities and newly incoming orders can be accommodated in an agile manner.

Transparently tracking overlapping flows is crucial for efficiently exploiting all capacities. Through IoT-enabled infrastructure and RFID features, interregional synchromodal flows could be synced with higher density networks so that goods could be grouped effectively, while keeping loading and delivery times to a minimum. Similarly, traffic management systems of various network operators should be integrated toward using arcs more efficiently to reduce overall network congestion through better planning and route selection. Such data is necessary to enable real-time response modeling and further realistic and holistic models. With the growth in big data analytics, research into control-tower information technology needs, decentralized applications, as well as semantic data models will gain traction.

The dynamic shifting of modes often helps to improve the service level in the synchromodal context. Yet, it may not always be appropriate, as it can lead to deviations and longer lead-times given the fact that some route and mode switching could lead to hubs located further away from the order’s final destination (Ambra et al., 2019a). Thus, when considering such proactive solutions, spatial attributes and request urgency should also be taken into account, and weighed against the impact of deviations and switching on key performance indicators. Balancing these considerations is challenging due to many uncertainties and hidden consecutive processes, such as the objectives of other service providers and the location of their assets, working conditions, congestions levels, blockages, weather forecasts and similar contextual network information. The necessary transparency of the network and overview of assets may be attained with IoT technologies and geo-spatial network coverage (e.g., 5G), subsequently enabling remote control, information exchange and automation of assets. The next section touches upon this matter in more detail.

Digitalization and Data Sharing

The various modes (road, rail, and inland waterway) currently do not share integrated data platforms. This reduced interoperability, exacerbated by noncompatible software, hamper the creation of holistic synchromodal services at the national and international scale. For inland waterways, the European Rive Information Services (RIS) addresses the latter by acquiring and sharing dynamic information across borders. Since planning in a synchromodal setting is to take place as late as possible, planning and execution horizons almost align, making the reliance on real-time developments for adjustment vital. Real-time response modeling should be developed further, since switching and transporting disturbed or newly incoming flows comes with additional costs. To make the system financially viable, one may develop approaches that bundle disturbed flows with items that have a long lead time. Specifically, should a truck break down or other developments impede the transport of a given payload, the goods could be switched to a different mode at a terminal (loaded on a train/barge). The disturbed or newly incoming payload should, therefore, be combined with other shipments, potentially resulting in higher fill rates or in a new service.

The key to effective synchromodal transport is real-time visibility across levels and continuous track and trace beyond mere point-to-point monitoring. This includes the inventory and in-house processes of hubs, the state of infrastructure such as roads, rail, and inland waterways, and the status of all moving assets. Uncertainties can be further reduced through more data transparency and technologies increasing visibility. Synchromodality extends the more static intermodal approach by enabling dynamic planning and mode switching. Yet as data volumes increase, control towers as central information hubs, become necessary when providing a single reference point to terminals and assets for effective service integration and container allocation. Such control towers vary on the ground. There are port community systems (PCS) enabling exchange of information between stakeholders at a given port, as well as proprietary control towers run by a single logistics service provider (LSP) where the data is only exposed to their clients and contractors.

The biggest hurdle on the way to the envisioned holistic system is the currently fragmented landscape of applications ranging from various port community systems, field force automation tools, fleet and freight management tools, enterprise resource planning systems, and supply chain execution tools to terminal operating systems. A unified freight transport system (Fig. 4) will only be achievable when the various tools are made compatible and standardized and when the flows are monitored through control towers in combination with decentralized system solutions. In addition, the production and freight transport systems should be connected so that local flows can be linked to synchromodal corridors, to facilitate a positive modal shift by reaching a critical mass for barges and trains. Furthermore, synchromodal control towers should be supported by decentralized applications that take care of point-to-point tracking, freeing up capacities for the analysis of newly incoming orders in terms of their temporal and spatial attributes and transport needs.

In the EU, significant financial resources are being invested in the creation of the Trans-European Transport Network (TEN-T) consisting of nine main corridors. Conversely, these should also link up to local distribution and manufacturing systems and

Figure 4 Conceptual barriers and underutilized assets (red) to be improved by interoperable communications and transparency (green). Source: Adapted from ETP-Alice

enable synchromodal planning. However, as flexibility and real-time planning become more prominent, flows that are currently static and predictable may become less predictable in a world of continuous updates and shifting of contexts. For example, low water levels could trigger everyone to shift to road or rail, potentially resulting in adverse effects in other infrastructure sections. Therefore, algorithms should be developed that could account for such unintended cascading effects in other parts of the freight system.

Conclusion

Multimodal/intermodal freight transport has undergone various changes. The breakthrough with the “box” has facilitated the physical handling of goods (Levinson, 2006). The next step is to induce a breakthrough with the digital dimension, which should facilitate information exchange about the “box.” Data availability and accessibility can improve synchromodal models and planning tools in order to provide more flexibility, higher speed, reliability, and a transparent overview of ongoing freight transport processes; these are the aspects that hinder most shippers from using intermodal services. In fact, models and decision-making tools without real-time situational data are generic. With real-time data feeds, they become unique and more realistic. Synchromodal transport is an extension of intermodal transport with a premise to make the freight transportation system more resilient, flexible, and responsive to newly incoming orders, disruptions, and breakdowns. But most importantly, it should be perceived as another word for modal shift, in which case fragmented orders are bundled in a transparent manner, with a goal to create critical mass for barges and trains. Such developments will contribute to increasing fill rates of environmentally friendlier transportation modes and reduce the share of road freight transport. Nevertheless, trucks will remain to play a crucial role in last-mile deliveries, as the final delivery locations are rarely located in ports and terminals. In this regard, the last-mile transport carried out by trucks also needs to be accounted for, to reduce empty and half-empty truckloads. To conclude, the most recent synchromodal stage is an exciting trend that will reveal many new opportunities, but also problems. Nonetheless, the scientific community, transport users, transport providers and policy makers can expect many new developments in terms of models and applications that will, hopefully, contribute positively to the roadmap toward the 30% reduction of road freight transport by 2030 and 50% by 2050.

Introduction

Pipelines, or pipeline systems, generally refer to an interconnected network of pipes and related facilities used for transporting gas or liquids—typically fuels such as natural gas or hydrocarbon liquids such as crude oil—over long distances. Pipelines are a highly efficient means of inland fuel transport, connecting oil and/or gas producers at one end to refineries, retail gas distributors, or power plants at the other. Pipelines are often referred to as the oil and gas *midstream* because they connect upstream producers with downstream users (e.g., retail gas markets, oil refineries, etc.). This article reviews the basic engineering and economics of pipeline systems, giving particular focus to natural gas pipelines and oil pipelines, which make up the vast majority of existing pipeline systems worldwide. Also included are short sections reviewing basic pipeline safety considerations and the role of pipelines in geopolitics.

Pipelines are of central importance to the overall hydrocarbon fuel value chains. Fig. 1 depicts a simple schematic diagram of these value chains. The gas value chain begins at the point of production, or wellhead, from which gathering pipelines deliver raw gas to nearby processing plants. These processing plants separate out natural gas liquids, water, carbon dioxide and other inert gases, and various impurities, and then feed a homogeneous finished gas product consisting primarily of methane, ethane, and propane, into long-distance transmission pipelines, which transport the gas to various end users. Alternatively, liquefied natural gas (LNG) may be imported via specialized import terminals, which, after regasification, feed into the long-distance transmission system. At various points along the pipeline system, gas may be held in storage in natural underground caverns or pressurized tank farms. In the United States, storage facilities are regulated as part of the overall interstate pipeline transmission system. Large mainline industrial customers—primarily gas-fired electric power generators—receive gas directly from the long-distance transmission system via ancillary lines. Some gas may also be delivered to LNG export terminals. The largest users of gas are local distribution companies (LDCs) and gas-fired power plants. LDCs receive gas from the long-distance transmission system at specialized hubs called “city gates.” From there, gas is delivered to homes and other retail customers via smaller distribution pipelines.

The oil value chain begins with crude oil. Domestically produced crude oil may be refined locally or shipped via long-distance pipelines (or by truck or rail) either for export or for delivery to major refining centers. Imported crude oil may be shipped via pipeline or delivered directly to the major refineries. Refineries process the crude oil into various derivative petroleum products (e.g., various types of gasoline, diesel, heating oil, lubricants, and a range of petrochemical precursors), which are then shipped via petroleum products pipelines, truck, or rail to petroleum products markets.

The world’s first oil and gas pipelines were built in the United States during the second half of the 19th century (American Petroleum Institute, 2019). At that time, western Pennsylvania was the center of the early oil industry. In 1863, a group of oil producers built a 9-mile wooden pipeline to a nearby rail station in order to circumvent the regional monopoly position in local oil transportation held by the *Teamsters* (organized teams of men driving horse-drawn carriages who transported barrels of oil and other goods). The first successful natural gas pipeline—2 inches in diameter and just over 5 miles long—was built in 1872 to transport “associated” gas to the Titusville, PA town center from a nearby oil well. The first long-distance oil trunk line was the *Tidewater* line, built by independent oilmen in 1879 to compete with aggressive oil baron John D. Rockefeller’s stranglehold over oil transportation (soon thereafter Rockefeller purchased a half ownership stake in *Tidewater*). The first long-distance gas pipeline was built in 1891 to carry gas to Chicago from fields in Indiana. Today, most countries around the world have at least some type of pipeline system (or systems) for transporting oil, natural gas, refined petroleum products, or simply water. The most extensive oil and gas pipeline systems in the world are located in the United States and Russia (Table 1).

The world’s largest pipeline system is the US natural gas transmission and distribution network, which comprises nearly 2 million km of gathering, transmission, and distribution pipelines. The overall US natural gas market, however, is divided into three distinct sectors—production, transmission, and distribution. Fig. 2 shows maps of the US long-distance natural gas pipeline transmission network (gathering and distribution lines not shown). This network comprises roughly 500,000 km of high-capacity pipelines

operated by over 200 independent firms, including over 1,400 compressor stations (not shown) and around 400 underground storage facilities (Fig. 3). Nearly 70% of these long-distance gas pipelines are classified as interstate pipelines, and are therefore regulated federally (Oliver and Mason, 2018).

Basic Engineering

The engineering aspects of oil and gas pipelines are quite similar (Meisner and Leffler, 2006). Both oil and gas are fluids. A fundamental characteristic of a fluid is that it conforms to the shape of the vessel in which it is contained, be it a storage unit or a pipeline. The key differences between oil and gas are that (1) gas is considerably less dense and more compressible than oil; and (2) a liquid settles by force of gravity, whereas a gas fills a volume. This means the parameters that govern the flow of either fuel through a pipe are quite different, despite the underlying physical process being largely the same. The basic operational principle of a pipeline, in any case, is to pump fluid into one end of the pipe at pressure, which forces the fluid down the length of the pipe, from which it is extracted at the other end. In a gas pipeline, a compressor changes the pressure and gas density, generating flow. In a liquid pipeline, pumps increase the fluid's pressure while the density is not affected. Considerable energy may be required to generate the pressure needed to push a fluid through the length of a pipeline, and the longer the line, the greater the energy required, although pumping requires significantly less energy by volume than compression. Pressure is greatest near the pumping or compressor station, and fluid friction losses in the pipe cause pressure to decline as the fluid travels along the line—referred to as the *pressure drop* (Fig. 4). Particularly long pipelines often require multiple, strategically placed pumping or compressor stations to ensure adequate pressure along the full length of the line. Pressure—and the energy required to generate it—may also be affected by changes in temperature (for gases) or elevation (for liquids).

The most important feature of any pipeline is its *capacity*. A pipeline's capacity is defined as the maximum level of service, measured in energy or volumetric units (e.g., MMBtu of gas or barrels of oil) per unit time (typically expressed in daily increments), that it can maintain over an extended period, and is subject to various technological, safety, and regulatory constraints.^a The most important factors in determining a pipeline's capacity are its (inner) diameter and operating pressure. Diameter, of course, refers to the circular width of the steel tube used to form the pipe, which is fixed upon construction. Pressure, by contrast, is variable along the

^a From an economic or regulatory perspective, capacity typically does *not* refer to the maximum physical throughput capability of the system or segment on any given day, which can greatly exceed the pipeline's certificated capacity.

Figure 3 US underground gas storage facilities. Source: US Energy Information Administration.

Figure 4 Stylized graph of the pressure drop along a pipeline segment.

length of the pipeline and depends on a number of factors such as pipe pressure rating, corrosion, and other safety considerations. Adding a pump or compressor increases operating pressure. A pipeline's *maximum allowable operating pressure* (MAOP), as the term implies, is the highest pressure at which the pipeline is allowed to operate, as determined by the jurisdictional regulator. The MAOP may change both along the pipeline and over time depending on its initial design characteristics (e.g., pipe wall thickness) and subsequent safety inspections. In the United States, for example, the MAOP for gas pipelines is determined by US Department of Transportation safety regulations, and is set considerably lower than its maximum design pressure. For safety reasons, the US Department of Transportation requires the MAOP to be lower in more densely populated areas (Oliver, 2015).

For a pipeline of a given diameter operating at a given pressure, the hydraulic properties of the fluid being transported also greatly affect flow rates. Such properties include density, viscosity, and vapor pressure (Meisner and Leffler, 2006). Oil, gas, and other hydrocarbon fuels vary significantly in these and other hydraulic properties. A fluid's density, viscosity, and other fluid properties can be calculated from an *equations-of-state* empirical model relating key fluid properties. *Density* refers to mass per unit volume, which depends on temperature, pressure, and fluid composition (or compressibility). A fluid's density is typically measured by pipeline operators in terms of *specific gravity*, defined as the ratio of the fluid's density to the density of a reference material (e.g., air for gas, water for liquid, etc.).^b *Viscosity* is defined as a fluid's internal resistance to flow (i.e., to pipe-wall friction); the higher a fluid's viscosity, the more energy is required to push it through a pipe. Viscosity is partly related to density, in that more dense fluids tend to be more viscous. The *vapor pressure* of a liquid is defined as the pressure exerted by a vapor in thermodynamic equilibrium with its condensed (i.e., liquid) form at a given temperature in a closed system. Vapor pressure and *dew point* are important for both gas and oil pipeline operations. For gas pipelines operating at a given temperature, when pressure and temperature drop below the dew point of (naturally occurring) heavier molecules such as ethane, butane, or water, they turn to liquids, which can block flows and damage compressors or other equipment. For oil and petroleum products pipelines, if the operating pressure drops below the vapor pressure of the particular fluid, this allows bubbles of vapor to form, which, similarly, can be damaging to pumping stations, meters, and other equipment.

The flow rate of a pipeline segment transporting a compressible gas can be calculated as a function of its diameter and length, the injection and withdrawal pressures, and several other parameters including the gas's specific gravity and compressibility factor. Mokhtahab et al. (2015) provide the following simplified form for the general flow equation over a pipeline segment:

$$Q = C \left(\frac{T_b}{P_b} \right) D^{2.5} \left(\frac{P_1^2 - P_2^2}{f \gamma_g T_a Z_a L} \right)^{0.5} E,$$

where Q is the standard flow rate measured in ft^3/day ; C is a constant that is adjusted for the volumetric unit used (77.54 for ft^3); T_b is base temperature in R ; D is the pipeline's internal diameter in inches; P_b is the pressure base in psia; P_1 is initial pressure in the pipe in psia; P_2 is terminal pressure in the pipe in psia; f is Moody's friction factor; γ_g is gas specific gravity; T_a is the mean flowing temperature of the pipeline in R ; Z_a is the average compressibility factor, L is the pipeline's length in miles; and E is a flow efficiency factor. In practice, specialized software tools are used to determine flow rates based on an advanced computational calculation of the complex pipeline system with all its boundary conditions.

The flow of an incompressible liquid such as oil or water is simpler, but still depends on a host of pipeline features and fluid characteristics, requiring sophisticated software tools to calculate local flow rates from complex pipeline models and the transient boundary conditions. First, the degree of *turbulence* of the flow within the pipe is determined by the *Reynolds number*:

$$\Re = \frac{\rho V D}{\mu},$$

where ρ is the fluid's density; μ is the fluid's dynamic viscosity; V is the cross-sectional mean velocity of flow inside the pipe; and D is the pipe's inner diameter. A more turbulent flow has a higher Reynolds number. Computing the flow rate requires first computing the average point velocity along the length of the pipe, $\bar{u}$, which depends on both pressure and the degree of turbulence. The flow rate can then be calculated as:

$$Q = 2\pi \int_0^a r \bar{u}(r) dr,$$

where a is the pipe's radius. In short, the flow volume rate equals velocity multiplied by the pipe's cross-sectional area. See Liu (2003) for a complete exposition.

Basic Economics

Pipelines exhibit *economies of scale*. This means that, all else being equal, a larger pipeline can transport fuel over a fixed geographic distance at a lower average cost than a smaller pipeline. These cost economies emerge over two margins (Oliver, 2015). The first is

^b For example, natural gas has a specific gravity ranging from 0.55 to 0.7, or 55%–70% of the mass of the same volume of air, depending on temperature. Crude oil at 60°F (15.56°C) has a specific gravity of roughly 0.9, or 90% of the mass of the same volume of water.

the fact that a pipeline's capacity—and therefore its throughput—can be increased for a less-than-proportional increase in *fixed cost*. Fixed costs are primarily those related to pipeline capital investment (e.g., construction costs), but also include other costs such as those related to regulatory compliance or obtaining right-of-way. Empirical research has confirmed, for example, that gas pipelines exhibit short-run economies of scale in production, as throughput can be increased at a less-than-proportional increase in pipe and compression capital costs. The second margin is that the *variable cost* of shipping a unit of fuel typically decreases as the capacity of the pipeline increases (Yépez, 2008). Economies of scale in production are important, as they generate productivity growth over time.

Pipelines also exhibit *economies of scope*. Economies of scope exist in a production process when the unit costs of producing two or more different goods or services in combination are lower than would occur under separate production processes. In the pipeline network setting, point-to-point transmission between different geographic locations on the network is analogous to the production of different goods or services in a traditional economies-of-scope model. Thus, scope economies exist when cost savings emerge as deliverability is expanded spatially to serve a greater number of geographically dispersed customers. This is easily illustrated by a simple but intuitive example of three network nodes—A, B, and C—spatially distributed along a roughly linear geographic arc, such that B lies between A and C. Transmissions from A to B, from A to C, and from B to C comprise three distinct services. Clearly, it is less costly to build a single transmission line from A to B to C that can provide all three services simultaneously than to build three separate lines connecting A to B, A to C, and B to C. In this sense, economies of scope exist in expanding a pipeline network spatially.

As a result of economies of scale (and, to a lesser extent, economies of scope), pipelines typically have significant market power, and in many (but not all) cases are considered to be local natural monopolies over their respective routes. A natural monopoly is defined in economics as a situation in which a single firm or supplier can satisfy the entirety of market demand at the lowest cost. This is true of many pipeline transmission routes. As a result, pipelines are typically either state-owned monopolies, as is the case for many European gas pipelines, or, if privately owned, are subject to price regulation, as is the case with US oil and gas pipelines. In many cases, pipelines are also subject to *common carriage* obligations, which prohibit discrimination against customers in terms of either prices or access. A notable exception is US gas pipelines, which are categorized by regulators as private carriers.

A fundamental aspect of the economic relationships pertaining to pipeline investment and transmission is that of *asset specificity* (Makholm, 2012). A pipeline is a capital investment whose economic value is specific to a single type of transaction—for example, transporting fuel from one geographic point to another—but which is otherwise essentially valueless. Asset specificity often leads to what economists have referred to as the “holdup” problem. In complex economic relationships with transaction-specific assets and incomplete contracts, a prior commitment made by one party may increase the rent-extraction capability of another party at subsequent stages. In the pipeline context, consider an example in which a gas producer sells gas to a pipeline, which then ships the gas and sells it to a single retail distributor at a bundled delivery price that covers both transmission and the value of the gas commodity itself.^c If the gas retailer has no other means of procuring gas, then in the absence of either regulation of, or a binding contractual agreement over, the price paid for transmission and resale of gas, the pipeline might be able to “hold up” the retailer by raising the bundled price of gas after the pipeline has been built.

Because of the asset specificity problem, the risk of holdup means the success of a pipeline project depends on cooperation between upstream suppliers (e.g., oil and gas producers), the pipeline, and downstream buyers (e.g., refineries, retail gas distributors, etc.). Once investment in the transaction-specific pipeline asset is sunk, investors face the risk that a party occupying a different position in the value chain might engage in “holdup” style rent-seeking behavior. This creates a considerable barrier to investment, the only two remedies for which are (1) long-term contracts between the pipeline and its upstream and/or downstream stakeholders regarding future revenue streams, or (2) vertical integration. Many pipeline systems around the world are vertically integrated joint ventures owned by oil and gas companies (as is the case for US crude oil pipelines, e.g.).

The US interstate gas pipeline network stands alone as the most economically competitive pipeline system in the world, largely due to the regulations enforced by the US Federal Energy Regulatory Commission (Makholm, 2012). Gas pipelines in the United States are investor-owned, privately operated facilities. Access to segments of point-to-point transmission capacity is allocated via long-term contracts between the pipeline companies and their “firm” customers. These contracts grant firm customers guaranteed access to a specified portion of a pipeline's capacity at a regulated price. Capacity rights have become a fully transferable, freely traded commodity in a largely competitive market for gas shipping services. This enables firm pipeline customers to either utilize their contracted capacity to ship gas or to sell the rights to its use to other shippers at an unregulated price in a secondary “capacity release” market.

Another key consideration in pipeline economics—particularly on a pipeline network that allows competitive point-to-point transmission like the US gas pipeline network—is the effect of congestion on market prices in the commodity market served by the pipeline infrastructure (Oliver et al., 2014). Importantly, at any given point in time a pipeline's capacity is fixed—that is, it cannot be increased incrementally in response to an increase in transmission demand. Congestion occurs when the demand for shipping services over a given pipeline route exceeds the capacity of the pipeline. When available space over the pipeline route is plentiful then, in the absence of any other idiosyncratic service interruptions, the difference in the commodity price between the points of receipt and delivery should equal the marginal cost of transmission. When available space becomes scarce and the pipeline is congested, competition for capacity drives the market price of transmission above the marginal cost, allowing owners of the rights to

^cThis was the standard industry practice for US gas pipelines throughout most of the 20th century, until the market was restructured by regulators in the 1990s.

that capacity to capture potentially large congestion rents. Such congestion rents depress the commodity price at the point of purchase (e.g., the wellhead) and drive up the commodity price at the point of sale (e.g., the city gate), which has salient consequences for economic surplus in the commodity market served by the pipeline.

Additional Considerations

Pipeline Safety and Integrity

Pipelines are statistically quite safe and reliable. Spills, leaks, and other accidents are comparatively rare relative to other means of fuel transport. However, they do occur, and major incidents can be extremely dangerous and/or environmentally damaging. Significant failures tend to make national or even global headlines, and the risk of such failures lead many to oppose pipeline construction through or near their communities.

There are several reasons a pipeline might fail. Remarkably, as [Kandiyoti \(2012\)](#) reports, over a third of all pipeline incidents are caused by *third-party* action, either negligently or intentionally. For example, a pipeline may be struck accidentally by an excavator. Or, in countries beset by violence and political instability, pipelines are routinely targeted by oppositional groups seeking to interrupt operations as a means of affecting some sociopolitical agenda. Operational reasons for pipeline failure include pipe corrosion, material failures (e.g., faulty welds), and mechanical failures. In yet other cases, damage may be caused by natural phenomena like earthquakes or hurricanes.

Both private industry groups and public regulatory agencies take part in determining operational safety rules and standards. Such industry groups include the Association of Oil Pipelines (AOPL) and the Interstate Natural Gas Association of America in the United States and the Conservation of Clean Air and Water in Europe (CONCAWE) in the European Union. Federal regulation of US pipeline operations is administered by the US Department of Transportation, Office of Pipeline Safety. No such body exists in the EU as a whole; operational safety regulations in Europe are administered at the national level. As a general rule, regulatory bodies require pipeline operators to maintain detailed *pipeline integrity management systems* (PIMS) and *pipeline safety management systems* (PSMS) that provide a comprehensive, integrated framework for pipeline asset management. Such operational standards minimize the risk of minor leaks and other, more significant failures, ensuring safe and reliable pipeline operations within the bounds of public tolerance ([Revie, 2015](#)).

Pipelines and Geopolitics

Because oil has been a lynchpin of global geopolitics since World War II, pipelines themselves have regularly been the focus of geopolitical tensions, particularly when they cross national boundaries. Nowhere was this more apparent than in the Middle East during the post-World War II era of the 20th century. Western developed economies—primarily the United States and Great Britain—were ravenous for oil supplies, and oil-rich Middle Eastern countries (e.g., Iraq, Iran, Saudi Arabia, etc.) were poised to deliver it. The geographic locations of many Middle East oil fields dictated that vast transport cost savings could be gained by building pipelines to deliver oil to tanker terminals along the Mediterranean. The alternative was to load tankers in the Persian Gulf, which were then forced either around the Arabian peninsula and through the Suez Canal or, even worse, around the southern cape of Africa. To reach the Mediterranean, however, such pipelines required passage through countries such as Syria, Jordan, Turkey, and Israel. Geopolitical tensions flared over a variety of issues including proposed pipeline routes, transit fees, and fuel prices, as well as over risks of service interruptions, sectarian violence, and even outright political blackmail ([Kandiyoti, 2012](#)).

More recently, oil and gas pipelines have taken center stage in Eurasian and south Asian geopolitics. After the dissolution of the Soviet Union in the 1990s, the Russian Federation found itself in a compromising position with respect to its own oil and gas exports to Europe, as major pipelines crossing former Soviet republics (e.g., Ukraine, Belarus, Kazakhstan, and the Baltic states) were claimed and nationalized by the newly independent nation-states. This has led to significant geopolitical wrangling between fuel-hungry European countries, Russia, and the intermediary nations over new pipeline projects and transit fees on existing lines. In South Asia, India has long sought to increase its gas imports by proposing pipelines from both the east (from Myanmar through Bangladesh) and the west (from Iran through Pakistan). Neither has yet been successfully implemented (or even agreed upon by the intermediary nations and other interested parties) due to seemingly intractable geopolitical disagreements ([Kandiyoti, 2012](#)). Anytime a major pipeline project requires a border crossing, it forces the international stakeholders to come to terms about a number of important factors—a difficult proposition when such neighboring countries already experience tension with regard to other, sometimes long standing, geopolitical issues.

Acknowledgment

I thank Klaus Brun of the *Elliot Group* for a number of helpful suggestions and clarifications regarding the section on pipeline engineering.

The Emergence of 3D Printing

3D printing (3DP) is a set of technologies that allows users to create products using digital models and an additive, layer-upon-layer manufacturing process. This new form of manufacturing is a marked shift away from shaping products from raw material as desired or from subtractive manufacturing methodologies, that is, constructing objects by cutting material away from a solid block of material. Trend watchers had already claimed that 3DP would lead to the next industrial revolution ([Economist, 2016](#); [Rifkin, 2011](#)). Initial growth figures (2014–2016) did not match these expectations, resulting in disappointment ([Deloitte, 2019](#)). The last couple of years saw an increase in growth because of more diverse 3D printable materials (moving from plastics to metals), higher printing speed, and a gain in printing volumes. Short-term expectations already envision that the worldwide 3D industry will grow steeply, from \$7.3 billion in 2017 to a forecasted \$15.8 billion in 2020, and \$35.6 billion by the year 2024. The growth is expected to come from more industrial 3DP systems, rather than desktop printers being sold ([Wohlers Report, 2019](#)).

3DP has been around for some time in the form of printed dental products, and has been adopted in other sectors that value production in small batches like hearing aids, and tailor-made jewelry and apparel ([Rogers et al., 2016](#)). In the context of product development in the automotive and aerospace industries, additive manufacturing has been used in the form of “rapid prototyping,” that is, to make prototypes in a relatively fast way ([Bradshaw et al. 2010](#)).

Two recent developments are changing the scene of 3DP. First, the quality of additive manufacturing is increasing rapidly. Traditionally, 3DP was associated with lower quality, related to issues like geometric repeatability (degree to which a digital image can be reproduced), surface quality, and fatigue resistance ([Huang et al., 2016](#)). Scientific and technological advances are currently overcoming these issues ([Gausemeier, 2014](#); [Ngo et al., 2018](#)). Second, the introduction of relatively cheap desktop 3D printers, such as RepRap, MakerBot, or Ultimaker, has made it possible for consumers to produce personalized home products such as jewelry and bicycle parts ([De Jong and De Bruijn, 2013](#)). With this, 3DP is moving from factory-based rapid prototyping to home fabrication ([Rayna and Striukova, 2016](#)).

3DP is thus associated with a more tailor-made, distributed way of manufacturing which, if successful, is bound to have repercussions on transport, supply chains, and logistics. But what is 3DP, how will it influence consumer wants and needs, location choices and transport resistance, and how will 3DP impact society? What are the repercussions for the transport and logistics sector? What is the state of knowledge, and which challenges are looming due to the emergence of 3DP? This article aims to answer these questions, of course taking into account the fact that the emergence of 3DP and its consequences are subject to a high degree of uncertainty.

The Concept of 3D Printing

The distinctive element of 3DP is building products layer by layer, rather than shaping from material (through forging, casting, stamping and molding) or subtracting from a block of material (through carving). 3DP should be understood as an aggregate of three elements: (1) the additive process technique, (2) the design and/or scanning software, and (3) the materials used ([Fig. 1](#)). The emergence of 3DP can be understood as an innovation pathway in which new developments are happening on all of these three elements, as well as in the combinations of these elements ([Robinson et al., 2019](#)).

Figure 1 The three main elements of 3D printing. Source: Adopted from Robinson et al. (2019)

The first working 3D printer built in 1986 by Charles Hull was based on stereolithography. Since then, various additive process techniques [(1) in Fig. 1] have been introduced (Table 1). The movements of the printers, as well as the size and form of the successive layers that need to be printed to fabricate the 3D object, are dictated by 3D modeling software, often in the form of computer aided design (Griffiths, 2002).

Influence of 3D Printing on Transport and Logistics

The influence of 3DP extends from manufacturing to include changes in logistics and transport. The recent cost reduction and availability of easier-to-use printers have led to expanding the customer base to also include households, schools, libraries, and so on. Such an expansion might result in a decentralization of production (Holmström et al., 2010). The transition from centralized to decentralized manufacturing has repercussions for transport flows (Ford and Despeisse, 2016) and related supply chain management and business models of involved companies (Bogers et al., 2016).

To better understand the potential influence of 3DP on logistics, a literature review was conducted of 93 scientific articles and 12 reports of leading consultancies. Based on the review and a survey amongst experts on 3DP and logistics, a model was created that

Table 1 Summary of different 3D printing techniques

Technique	Short description	Application areas	Introduced since
Stereolithography	Photochemical process of UV laser causing monomers to link together to form polymers	Biomedical Prototyping	1986
Fused deposition modeling	Thermoplastic material filament fed through a moving printer extruder head, the shape of which is digitally controlled to define the printed object	Rapid prototyping Toys Advanced composite parts	1988
Powder bed fusion	Fusing thin layers of powder with use of lasers	Biomedical Electronics Aerospace Lightweight structures (lattices) Heat exchangers	1993
Inkjet printing and contour crafting	Powder pumped and deposited in the form of droplets via a nozzle to form a continuous pattern	Biomedical Large structures Buildings	1993/2011
Direct energy deposition	Energy source like lasers is focused on a substrate simultaneously material	Aerospace Retrofitting Repair Cladding Biomedical	1995
Laminated object manufacturing	Adhesive-coated material (paper, plastic) is glued together and cut into shape	Paper manufacturing Foundry industries Electronics Smart structures	1996

Source: Based on Ngo et al. (2018)

Figure 2 Conceptual model for the impact of 3D printing on logistics and eventually on accessibility, the environment and safety. Source: Adapted from Boon and van Wee (2018)

conceptualizes the influence of 3DP on logistics, and subsequently on societal impacts in terms of accessibility, traffic safety and sustainability (Boon and van Wee, 2018). The model is shown in Fig. 2.

Each element of the model can be elaborated upon, first zooming in on the influence of 3DP on wants and needs, location decisions and transport resistance. Subsequently, transportation volumes and technologies are addressed and, finally, the way in which accessibility, sustainability and safety are influenced.

Wants and Needs of Consumers and of Producing Companies

3DP was originally used to produce one-offs in professional settings like the abovementioned rapid prototyping in aerospace and car industries, or creating personalized models of skulls that can be used for preparing for complex surgery. Increasingly, 3DP is utilized to cover both prototypes and finalized products. The latter include examples like in-ear hearing aids and dental parts, as well as small consumer products, like jewelry and toys. Close to adoption are applications like spare parts in the aircraft and surgical industries. Consumer products are especially restricted in their impact and some authors claim that 3DP will remain having a limited effect (Fawcett and Waller, 2014; Gress and Kalafsky, 2015). More complex products remain comparatively rare, because of questionable efficiency and added-value to consumers (Mckinnon, 2016).

Literature and the experts who were surveyed were in agreement about the fact that mass-customization will become more important. There are different points at which the customer may become engaged in the supply chain, at each stage of the supply chain: design, purchasing, fabrication, assembling and distribution (Gosling et al., 2007). 3DP plays a significant part in customer-specific design and manufacturing, since it has the possibility to pursue product customization and a fast response to customer needs, as a result of flexibility and adaptability (Bhattacharjya et al., 2014; Chan and Chan, 2010; Christopher and Ryals, 2014; Janssen et al., 2014; Lopes da Silva and Vicente, 2013). 3D-printed prototypes can help increase user understanding early in an innovation process, decreasing time-to-market and risks of non-adoption (Kanto et al., 2014; Romero and Vieira, 2016). Companies might respond by making their supply chain and related production capacities more flexible and agile (Sasson and Johnson, 2016).

A related development is the rise of 3D platforms that offer, amongst other things, free-to-use design files (www.thingiverse.com) or offer a place to share 3DP capacity (www.3dhubs.com). Such platforms can increase the possibilities of personalization and the ability to deliver to the “long-tail” of consumer needs (Bogers et al., 2016). Moreover, these platforms are often two-sided, that is, consumers both use the presented products (e.g. designs) as well as offer their own creations. As such, 3DP ties into the development of consumers becoming producers, acting as “prosumers” (Chen et al., 2015; Rauch et al., 2016).

The experts interviewed (Boon and van Wee, 2018) were divided on the issue as to what extent consumers are willing to really manufacture a wide range of products at home, or whether new needs for different kinds of products will emerge. Also, opinions about the frequency of buying were split: some experts say that frequency will increase, because customized products follow trends

and are disposed of more quickly; additions are replaced more easily. Others claim frequency will decline, because customized products do not need to be replaced and if broken, small parts can be reprinted.

Location of Production, Clients and Distribution

3DP advances mass customization and personalization (Bhattacharjya et al., 2014; Mourtzis and Doukas, 2013). The question central to many articles and trend reports is to what extent 3DP leads to distributed production. Two extreme scenarios can be sketched: decentralized versus centralized manufacturing (Li et al., 2017). Most publications envisage that 3DP will result in more decentralized manufacturing, offering greater proximity to customers and responsiveness to market needs (Fornasiero et al., 2010; Manners-Bell and Lyon, 2012), possibilities to cut out middlemen (Jia et al., 2016), and even the reshoring of manufacturing to high-income countries (Campbell et al., 2011). Designs travel digitally (Janssen et al., 2014) and as such can replace the movement of products (Garrett, 2014).

In the decentralization scenario, the locations of 3D printers will vary, ranging from “print shops” serving markets at a continental scale, city- or neighborhood-level hubs to printers located at consumers’ homes (Rauch et al., 2016; United States Postal Service Office of Inspector General, 2014). Ryan et al. (2017) produced a different, yet related taxonomy of decentralized 3DP scenarios: mobile, in-transit 3DP; 3DP for standardized spare parts; local and regional factories; craft businesses, like “fablabs,” and personal manufacturing.

An in-between scenario is that 3D “mini-factories” are located at local service providers such as libraries, community centers and post offices, as such mimicking 2D printing of photos and books. It is also expected that 3D logistics service providers will enter the additive manufacturing market within the next ten years (Durach et al., 2017). Hub-level operations have the advantage over home-based printing, because 3D printer (machine) operation, post-processing, quality control and (consumer) packaging require investments and expertise that home-print consumers are not going to develop. Much is expected from the product customization, agility and even complexity that 3DP hubs can yield, which are associated with specialization, lower time-to-market and even lower costs (Rogers et al., 2016).

Some industry watchers still emphasize the importance of centralized production. High-volume, low-added-value production will remain more efficient in centralized factories (Holmström et al., 2010; Li et al., 2017). Also, low-volume and high-added-value manufacturing require support infrastructure and specialized human resources (Gress and Kalafsky, 2015). The degree of centralization involves a complex interplay of economies of scale, as well as user requirements, regarding flexibility, adaptability, demand uncertainty, supply uncertainty, and capacity utilization. For example, in spare part management in the field of aircraft maintenance there are parts that are not used very often, “slow-moving parts,” yet when required they are needed fast. In these cases, 3DP might provide a solution (Fawcett and Waller, 2014; Holmström et al., 2010; Huang et al., 2013).

In the end it may very well be that the two “extreme” scenarios are combined and are deemed complementary. A hybrid scenario could be that more advanced 3DP will (mainly) be done at centers, and that simpler printing will be done at home. For such hybrid scenarios to be pursued, it is important to think about communication, information exchange, intellectual property rights, and quality control between centralized and decentralized entities. Advancing digital innovation may facilitate managing this (Durão et al., 2017). Companies will vary in the business models they adopt, but experts expect the hub model to be favored over competing approaches and to emerge as the dominant business model (Boon and van Wee, 2018).

Transport Resistance

The location of 3DP dictates the nature and size of transport flows. 3DP taking place closer to home is related to a decrease in distribution between manufacturing and end users (Janssen et al., 2014; Tuck et al., 2007). Even shipping and air cargo volumes might come down (Barz et al., 2016; Manners-Bell and Lyon, 2012). As input to decentralized 3DP, shipments of raw materials will become more important. This would mean a shift from manufacturer–consumer distribution to the raw material supplier–manufacturer side (Gress and Kalafsky, 2015; United States Postal Service Office of Inspector General, 2014). Moreover, the transport of raw materials can be more efficient, since bulk delivery means less packaging and urgency, leading to a reduction of ton-kms and cubic meter-kms of freight movements (Mckinnon, 2016). Distribution networks will be organized more efficiently: with more nodes and more flexibility. Transport and logistics costs may come down as production happens closer to home and feedstock is transported more efficiently in the form of cartridges, leading to less air to be transported on the outbound-shipping part of the chain. Relatedly, 3DP has an impact on warehousing. Less inventory might result from less variety in input materials needed, less safety-stock, and consumers being dedicated in their needs (Mavri, 2015).

Still, some experts think that transportation costs may actually increase (Boon and van Wee, 2018; Durach et al., 2017). Raw materials will need to be shipped to 3D printers located at “mini-factories” or hubs. Then the distribution between hubs and consumers’ homes might spur short-distance “last mile” express delivery that is associated with higher flexibility in distribution and higher costs (Mohr and Khan, 2015). Even so, different types of costs can also balance each other out: for example, Westerweel et al. (2018) found that the higher design costs related to 3DP are offset by reduced after-sales logistical cost and lead-times.

Transport Volumes and Technologies

3DP might lead to the transportation of more raw materials, for example in the form of gels and powders contained in packaged cartridges. This, then, means a shift away from shipping ready-made consumer goods, the transport of bulk inputs for 3D printers will become more important and might mean less need for the use of containers. On the other hand, experts say that other emerging technologies, such as electrification and autonomous driving, are far more influential on how transport technologies of the future will look. An interesting, left-field idea is to have 3DP manufacturing onboard a driving truck, which opens up the possibility of creating products just-in-time for delivery (Ryan et al., 2017).

In terms of transported volume, there are reasons to assume that there will be a decrease because of extended product-life-in-use, less air to be transported, and a reduced number of kilometers in the last mile. There are also reasons for an increase in transport volumes as there is more material that needs to be cut out, and subsequently returned. The timing of deliveries to consumers might change. On the one hand, there may be more deliveries outside office hours, whereas on the other, brand new ways of dispatching can emerge, such as smart letterboxes.

Societal Impact: Accessibility, Safety, and the Environment

The literature has been silent about the effects of 3DP on traffic safety, accessibility, infrastructure needs, and the indirect effects on passenger transport. Concerning welfare, income, and employment, 3DP may be regarded as having a potential disruptive impact on the global transport sector (Bogers et al., 2016). The total system costs may not drop because labor and transport costs are communicating vessels (Chan and Chan, 2010; Manners-Bell and Lyon, 2012). For example, 3DP might lead to “reshoring” of manufacturing to high-income countries, especially as 3D printer hubs are to be located closer to customers (Frazier, 2014; Janssen et al., 2014). At the same time, this would require the creation of highly skilled jobs in these hubs (PWC, 2014). Traditional outsourcing countries may not be disadvantaged by reshoring, as experts claim that they are increasingly becoming capable to become frontrunners in 3DP as well (Gress and Kalafsky, 2015).

In terms of the environmental impacts of 3DP, there are model-based studies that hone in on material usage and waste (Campbell et al., 2011; Huang et al., 2016; Romero and Vieira, 2016; Barz et al., 2016; Garrett, 2014; Li et al., 2017; Lopes da Silva and Vicente, 2013). Less is written about logistics and transport-related environmental impact. Some publications make tentative predictions that emissions and oil use will be reduced (Bhattacharjya et al., 2014; Ford and Despeisse, 2016). Proposed hypotheses are that due to production closer to home, long-distance transport can be reduced and distribution of raw materials can be made more efficient. Last-mile movements might increase but if they are done by low-emission vehicles, then this means less

Figure 3 Spectrum of possible 3D printing locations.

emissions (Chen et al., 2015; Rauch et al., 2016). 3DP might, due to its production-on-demand model, lead to reduced inventory waste and greater potential for recycling (Despeisse et al., 2017; Ford and Despeisse, 2016). On the other hand, the logistical network might also become less efficient: “a change from standard to individualized, highly responsive logistics services [. . .] will lead to less sustainable logistics systems” (Tavasszy et al., 2003).

Discussion

How the future of 3DP will look is largely dependent on the interactions between end-user needs and wants, location decisions, and transport resistance. 3DP is associated with the personalization of products and might tie in with developments like mass-customization. Of course, not all types of products are equally suitable for personalization and in some cases small batches are not (cost)efficient. Still, in some sectors like aerospace and medicine, small batch 3DP is widely adopted, and other sectors might follow suit. As such, 3DP is expected to result in decentralization, although the exact nature of decentralization is still open for discussion. One may see the location of 3DP as part of a spectrum, ranging from centralized production all the way through to home-based printing (Fig. 3). Obviously, the exact outcome is dependent on factors like type of product to be manufactured, type of material, etc. Since there are a wide variety of consumer needs as well as types of materials and products, most likely a hybrid scenario will unfold in which different forms of 3DP in different locations are coexisting.

The emergence of 3DP and the associated decentralization of manufacturing will impact the transport and logistics sector in several ways:

- Transport volumes might not necessarily decrease, but delivery times and transport costs are expected to decrease.
- In terms of transport flows and movements, distribution networks are expected to be organized more efficiently. Distributed manufacturing still means that raw materials need to be shipped to decentralized locations. However, the transport of raw materials is expected to be more efficient, as they are moved in bulk in forms like cartridges, leading to less empty vehicles.
- The way inventories are kept will change: the size of inventories might decrease, amongst other things, because goods are now made to order and because safety-stock is not needed. Especially in the area of service parts, there are new opportunities for the instantaneous production of spare parts. Associated with this is the fact that suppliers run less risk of keeping products in stock that are never sold.
- The roles and positions of companies in the value chain will shift. In some scenarios some intermediaries, such as wholesalers or even retailers, might become superfluous. Some shops will vanish altogether or change into places to showcase products. At the same time, companies might strategically make upstream or downstream movements. Logistics companies might move into decentralized production by opening 3DP hubs. For example, postal services can turn their post offices into printshops and use their distribution networks to provide last-mile deliveries (United States Postal Service Office of Inspector General, 2014). Another example is wholesalers starting to emphasize stocking and delivering raw materials needed for home-based printing.
- Even if the roles of the companies in the value chain remain unchanged, the exchange of information will be affected. 3DP emphasizes agile development, on-demand production and customization, which means that customers are increasingly submitting personalized designs, either created on their own, or based on designs available on internet platforms. Design information needs to be sent to the 3D printer and probably checked before manufacturing can begin. Related to this, control over intellectual property rights and unwanted products is a challenge, as design platforms consist of propriety designs and there was commotion about the creation of a design template for a 3D-printed gun.
- Thus digitalization is becoming more important, because the design of products may move from end users to printing hubs, or from centralized companies to near-shored printing hubs (Fig. 2). There is a large role for quality control in this process: decentralized production still needs to adhere to quality standards imposed by the company and/or the government (e.g. in the form of safety and the environment).

Concluding Remarks

This contribution set out to explore the influence of 3DP on transport and logistics. More specifically, it dealt with how 3DP will influence consumer wants and needs, location choices and transport resistance. It has also addressed what are the repercussions for society and, specifically, the transport and logistics sector. Experts and industry watchers claim that 3DP has the potential to disrupt industries, including the transport and logistics sector. 3DP is an emerging technology, meaning that many aspects, like demands, networks and the technology itself, are under development, malleable and uncertain. Crucial factors of 3DP are the decentralization of manufacturing locations and the on-demand and agile nature of consumer demand. These two cornerstones will influence the way supply chains are organized and how logistics is organized. In turn this might then influence transport flows and related impacts on society in terms of safety, accessibility and the environment, as well as the nature and survival of firms in the value chain of many industries. Monitoring of the developments of 3DP in relation to transport and logistics is crucial, because it might have consequences for infrastructure, regulation, the capacity of logistics hubs like ports and harbors, and many more.

Biographies

Wouter Boon is Assistant Professor in Innovation. He works at the Innovation Studies group that is part of the Copernicus Institute of Sustainable Development, Utrecht University. His research in the field of innovation studies focuses on the dynamics and governance of emerging technologies in science-based sectors, such as transport and life sciences. The theoretical focus of his work is on the role of user innovations, user-producer interactions, regulation, and knowledge production in emerging technology fields.

Bert van Wee is Professor in Transport Policy at Delft University of Technology, the Netherlands, faculty Technology, Policy, and Management. In addition he is scientific director of TRAIL research school. His main interests are in long-term developments in transport, in particular in the areas of accessibility, land-use transport interaction, (evaluation of) large infrastructure projects, the environment, safety, policy analyses, and ethics.

Motivations for a New Theory of Logistics Networks

To understand why and how the Physical Internet was proposed, this part starts with the context of logistics networks, how and why they are organized. The analysis of their efficiency shows their limits especially in regards to new challenges such as e-commerce delivery and sustainability.

The State of the Art: Fragmented Networks and Operations

Logistics networks are a heritage of proprietary networks developed in the 19th and 20th centuries and dedicated to companies, a car manufacturer or a retailer as examples, or a specific service like mail with postal services over a limited territory. As a result, there are as many logistics networks as there are combinations of companies and services. This organization was not an issue as volumes became concentrated due to mass production or distribution or in monopolistic services as mail. With the evolution of both industry and distribution toward just-in-time and multiple channels all over the world, needs have drastically changed at the end of the 20th century with the creation of logistics networks by postal operators and carriers and the development of logistic service providers (LSP). With the notable exception of the maritime shipping industry, which is highly concentrated, the logistics sector remains vastly highly fragmented even though it is concentrating over time. Furthermore, even with major players in the markets, services also remain fragmented with dedicated resources. An LSP will dedicate a warehouse to a customer and operate it independently of other activities; a courier company will not share resources for different levels of service and so on.

Despite the ongoing concentration in the sector, operations remain highly fragmented as the need for shipping becomes more and more fragmented, with just-in-time deliveries and the proliferation of distribution channels. The effect is not well described but a survey made in France by IFSTTAR (the French transportation institute) showed that the median shipment weight dropped from 160 kg in 1988 to 30 kg in 2004. At that time, this trend did not take into account e-commerce activity as it was completely marginal. So this trend is even further reinforced now.

A Major Consequence: A Low Level of Efficiency

The fragmentation of flows makes any consolidation and therefore, the creation of positive scale or scope effects difficult. The fragmentation of flows is not directly measured and there is no globally accepted indicator. The phenomenon could, however, be illustrated by example. Fig. 1 represents the flows of goods between two main retailer distribution centers and their common top 100 suppliers.

Figure 1 Flow map of two main retailers and their common top 100 suppliers located in France.

Figure 2 Analysis of truck's overall efficiency in the FMCG sector.

Another approach is to look at asset utilization rates. If there is no public information on the filling rate of warehouses, statistics can be found on the use of trucks. A 60% fill rate and 20% of empty km are common numbers in this regard. However, this falls far short of achieving overall efficiency. The overall efficiency for vehicles can be computed. As shown in [Fig. 2](#) based on [McKinnon et al. \(2003\)](#), the results show several main sources of losses and an astonishingly low level of 10% of efficient trips. [Fig. 2](#) indicates that compared to a perfect world, freight transportation could be performed with 10 times less trucks. Even if perfection is out of reach, the potential for progress remains considerable.

To cope with the inefficiencies now well known in logistics, one possible approach consists of pooling some resources—transportation means, warehouses, etc. This concept has been known for more than a decade, with real improvements in efficiency when applied. Generally, costs and CO₂ emissions are reduced by 25%, but the commitment required from companies to participate in such an organization is still a barrier against its generalization ([Cruijsen et al., 2007](#)).

New Challenges: Service Improvement and Sustainability

Despite low efficiency, logistics services are generally very good. They are affordable, reliable and delivery times have become shorter and shorter. So, they are more and more used. Economic development is coupled with the growth of flows. By 2050, economic development is anticipated to lead to an increase in freight traffic of more than 200% in Europe and North America and to nearly 600%. In Asia for maritime or surface freight ([ITF, 2017](#)). As a result, if nothing changes, this will lead to much more traffic than today and a much greater need for infrastructure. Even though more environmentally friendly vehicles are gradually being brought into service and products are being supplied closer to their places of consumption, it is clear that the current trend will not achieve the goals of sustainable development, starting with a 60% reduction in total CO₂ emissions. This would mean an almost complete decarbonization of the transport sector, including infrastructure. It seems out of reach on the basis of actual and foreseen technologies.

Figure 3 Emission factor and vehicle payload.

One might think that the solution to quickly delivering small quantities of goods would be to reduce the size of vehicles and accelerate their speed. This is, for example, the approach underpinning the potential use of drones. This approach, however, faces a major obstacle, that of scale effects. If it is better to have a small, well-filled vehicle than a bigger one, nothing can replace the efficiency of a well-filled big vehicle. This is not only true from the cost of transport operations point of view, it is also true for externalities and in particular for CO₂ emissions (Fig. 3).

This is where the antagonism between service improvement and impact on sustainability occurs. Indeed, if the acceleration of flows is reflected in the use of smaller scale means, the overall externalities of freight transport will increase. These include not only environmental impacts (air pollution, global warming, noise . . .), but also social costs (lost time, accidents...) which, ultimately, can represent a cost to society of the same order of magnitude as the cost of transportation itself in densely populated areas (European Commission, 2019). Under the current organization, therefore, there is a strong dilemma between a growing demand for fast deliveries, thus in smaller quantities, and the resulting environmental footprint. It is not a question of means of transportation, but a question of how demand is served by supply chains.

The Physical Internet

The previous analysis shows how logistics networks are organized and what results from them in terms of transport. This justifies finding new approaches to the organization of logistics activities that can help solve the challenges.

Origins

The origins of the Physical Internet are multiple. It has emerged naturally as the result of analyses carried out on the durability of logistic organizations and certain preexisting organizations described later. But the term Physical Internet comes from the title of a "classic" article on logistics published in *The Economist* in 2006 (Markillie, 2006) and once found by Benoit Montreuil was transformed into a research question. What would logistics be if it was designed as an internet? That is, as a set of interconnected networks and not as a set of independent heterogeneous networks. The generic question already has known answers in computing (the internet) but also in electrical energy, for example, electrical grid, and then smart grid. The question applied to logistics helps to rethink all logistics activities, but also helps to discover among existing practices those that could be considered as a beginning of the physical Internet.

The set of experiences and practices carried out in the field of horizontal collaboration to associate several companies to share logistics resources corresponds in part to the objectives of the physical internet to allow users to use shared resources with the benefits previously mentioned. However, each collaboration requires reinventing its content, which limits its development.

Another organization prefigures what could be the Physical Internet and the Dabbawallas. This refers to a distribution organization of home-cooked meals prepared in the morning and delivered for lunch at workplaces in Mumbai. The system

operates from identical boxes with a unique code that allows them to be routed to their destination in the midst of thousands of others and using all modes of urban transportation and multiple independent service providers (Thomke, 2012). This organization is very close to the internet physics, except that it provides only one service and is not connected to another place.

The last example concerns containerized marine shipments, which have evolved considerably since the standardization of containers and their fasteners, the twist-lock. This technical system has favored multimodal transport and the realization of logistical schemes using shared means. On the other hand, the logic of hub and shared transport usually stops at the port or is limited to railway lines in the countries where these networks are developed.

Definition

The core idea of the physical Internet is the interconnection of networks, which leads to a network of networks. The parallel with the digital Internet is obvious. The Internet is the network that encompasses all computer networks, but the means of this interconnection needs to be defined for logistics network to make it more tangible.

The definition was elaborated by Montreuil et al. (2012). It is the following: the Physical Internet is a global logistics system based on the interconnection of logistics networks by a standardized set of collaboration protocols, modular containers, and smart interfaces for increased efficiency and sustainability. The goal is efficiency, the means is the interconnection of logistics networks that involves standardization and protocols at four levels: physical, data, process, and legal to ensure compatible operations, regardless of the operator and the nature of the service provided.

This definition also limits the scope of the Physical Internet to logistics. The interconnection is established at (containerized) shipments in all aspects that affect them, but not beyond. Thus, a truck may be subject to a possible development to accommodate modular containers, but the road is not affected. However, a container-sorting center will have to be adapted to them for their handling and monitoring. In the same way, the commercial relationship between a supplier and his customer is not the object of the interconnection. On the other hand, an interconnection can strongly influence the design of truck trailers as well as how to manage a supply chain to take advantage of the potential offered.

Main Components

Physical

The equivalent of a digital packet for the physical Internet is a shipping unit: a container. Studies carried out in collaboration with industry, in the United States and in Europe, have shown that two layers of encapsulation between the products (packaged or not) and the means of transport or the manipulator are the maximum necessary. The first layer, the handling box is modular in external dimensions, stackable, and ensures the privacy and security of the goods, the second layer is how the transport container or interface fits with modular handling boxes, ensures the interface with the transportation means and protection from external conditions, if necessary. Both layers ensure handling productivity and are fully traceable. Fig. 4 describes the layers.

The standardization of containerization and associated handling tools is motivated by the current lack of widely accepted formats for cartons, the variety of pallet sizes and, consequently, the space lost in the stacks, the poor quality, the low productivity and the consumption of raw materials. In this respect, the study of the history of development of the maritime container is illuminating

Figure 4 Encapsulation layers in the Physical Internet.

Figure 5 Comparison of cost components for a shipment equivalent to one full container from Chicago to Nancy. Source: Original data from Levinson (2006).

(Levinson, 2006). After a difficult start, the acceptance of both 20 and 40-foot formats and the twist-lock has enabled the shipping and port industries to develop impressive productivity gains in 50 years. The reconstitution of the productivity gains by the evolution of the prices of the components of a consignment between Chicago and Nancy before containerization and currently shows the progress made possible by the standardization of the container and, conversely, the absence of productivity gains for land transport. See Fig. 5 for the numbers.

Data

One of the advantages of using a dedicated solution is to facilitate the monitoring and control of operations by interfacing the information system of the service provider and its client. However, there are now standards, such as EPCglobal, which make it possible to designate products, handling objects, consignments, and places in a unique way on the one hand and, on the other hand, there are independent monitoring solutions from the information system for products and shipments.

The development of passive tags (RFID) or active (Bluetooth) for short-field communication solutions, coupled with long-range solutions (LORA) based on multisectoral telecommunication infrastructures, will in the near future provide almost permanent tracking of unit loads, if necessary. This can be done independently of logistics operators and their information systems that will rely on the same sources of information. Fig. 6 illustrates a possible scheme, already tested. Finally, the deployment of 5G technology will make a qualitative leap while keeping costs low.

A common language and technologies are now almost ready to bypass the interfaces between existing information systems for the needs of the Physical Internet. Clearly, data ownership, access permissions, and management remain. Blockchain technologies could also provide interesting support for logistics operations within the physical Internet, thus ensuring the authentication of logistics transactions between logistics providers and their customers.

Process

The interconnection of processes allows one of the main functionalities of the physical internet, namely the routing of the logistics units (containers) from their origin to their destination as requested during the dispatch. This may be different from the final destination, because the Containers can be brought to a hub, stored and later brought closer to the final destination. So routing with the physical internet must be able to transport, but also store, on demand. The determination of these needs, however, depends on the management of the supply chain.

Virtually, a customer indicates where to place each of his handling boxes in space and time. The request can be very precise (e.g., a given warehouse on a fixed date) or more flexible (e.g., before a deadline in a geographical area, with a short deadline or on the contrary a longer one), with environmental requirements, etc. These are the criteria of each container that defines the expected service that will be evaluated individually and aggregated for each service and provider. The points and means used at each intermediate stage of the routing are left to the discretion of the operators to enable them to optimize the routing. Routing can be broken down into two main steps.

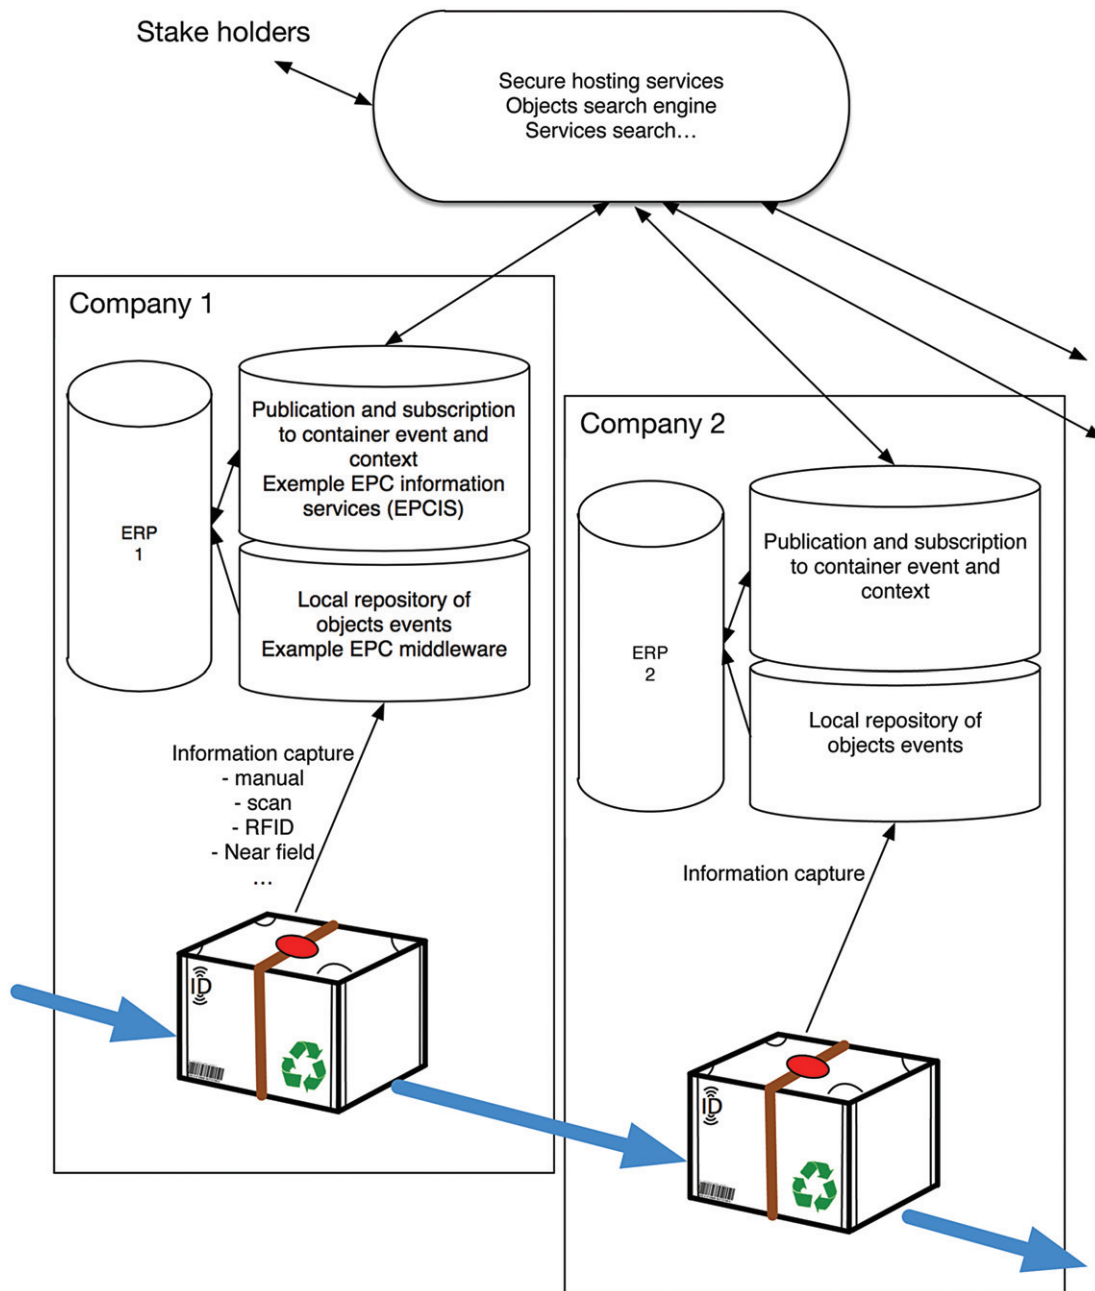

Figure 6 Digital tracking of containers in the Physical Internet.

The first step determines the path that includes transport services (network arcs) and storage and handling services (network nodes). For the verification of the feasibility and the fixing of a price offer, at least one end-to-end routing solution must be available. This solution may be frozen (booking) or otherwise remain flexible to allow adaptation to real conditions, or even an improvement of the initial routing solution. The second hypothesis implies a recalculation of the route according to the offers, but remains subject to the initial conditions. The initial solution and the following are calculated by conventional algorithms of shorter path for example. The services included in the search could be selected according to a minimum proven service level.

The second step concerns the actual allocation of the container to a specific service: transport, handling, storage, or a combination of these. At each stage of routing, a service provider must be determined and a transaction must occur to transfer each container with its specific needs. The selection of services for a set of containers arriving at a hub can be done with different purchasing solutions. Mechanism design, with combinatorial auction, has already been successfully tested in simulation. The main idea is that every time the best solution available is used, according to the requirements.

Legal

All logistic operations are covered by contracts in which the commitments and responsibilities of the stakeholders are established, including the case of outsourcing that is already widely used and internationally. In particular, this aspect has already been partly standardized by incoterms. The question is, therefore, whether these are sufficient or whether they will need to be amended and supplemented. It would seem that they are currently sufficient.

Another concern is the competition between LSP and the platforms that offer them. This point also mentioned in pooling is not yet resolved, but it is already noted in simulations that it could, on the contrary, make the market more dynamic and open.

Finally, the question of the governance of the physical Internet is often rightly raised. The Physical Internet being currently in the experimental phase and not yet deployed, the question can be postponed. However, the recent projects, pilots and exploitation of the concept suggest that centralized regulation already appears necessary, especially to label solutions as part of the Physical Internet. This will be the case for containers when a solution emerges, but also for identification codes or routing protocols.

The physical internet deployment represents a profound change in tools, systems, and processes as evidenced by the impact on the four levels described earlier.

Implementation of the Physical Internet

Simulation

The first implementations of the physical Internet were realized with simulation tools of supply chains and logistic networks, in order to understand how the theory could work on existing cases. That is to say, reproducing real cases of applications. This work was conducted in Europe, North America, and Hong Kong by independent research teams. The results obtained confirmed the hypothesis of a significantly more efficient organization. Thus, a large-scale simulation carried out in France and dealing with the flows of two distributors and their main suppliers, mentioned above, made it possible to show the impact on the flow structure, which is not only much more concentrated (Fig. 7), but also achieves improvements of more than 30% of filling rates, the possibility of making full trains or the reduction of 15% of t.km. In the end, there are almost 60% less emissions than with current technologies. The impact on inventories is identical, with gains of around 30% in quantity with distributed stocks that are supplying each other. As a result, the inventory network ensures product availability in place of a centralized safety stock. In all cases the service is preserved or improved.

Start-ups: Routing, Storage, and Open Services

Several start-ups and companies, most of them awarded during the annual International Physical Internet Conference or IPIC (www.pi.events), joined the approach and propose logistics services that implement part of the Physical Internet. In the case of routing, Mix-Move-Match and Collaborating Routing Center Services or CRC Services are used. They propose to operate routing services over existing logistics networks. Both companies have shown that multi-client, multi-recipient flow routing is working and that efficiency improvement ambitions are achieved even on limited scales.

Figure 7 Flow map of freight in interconnected logistics networks enabled by the Physical Internet.

From a storage perspective, much like online booking sites, several companies, such as Flexe, Stock booking or OGOShip, offer on-demand permanent or temporary storage in a multitude of warehouses with unused capacity. Even if these companies are specialized at the beginning, they are moving toward a wider range of services: storage, preparation, and transport, in order to provide more comprehensive solutions that remain based on the same principles of shared and on-demand resources. When these companies open and sell their technology which allows other logistics service networks to operate in a consistent manner and have operations that move from one network to another, then interconnection becomes a reality, as is happening in 2019.

Container Development

The physical internet is often associated with containerization and the first European project Modulushca has directly worked on the benefits, design, implementation and testing of modular boxes. This effort continued with the help of the CGF then GS1 Germany, which carried out a successful test of boxes of 60×40 for care products. This box is now being rolled out by the companies that participated in the development, with the idea of a generalization at European level.

At the level of transport containers, several solutions exist, starting with sea or air containers. However, there is no suitable solution for multimodal terrestrial transport, particularly for urban deliveries. A European project, Clusters 2.0, focuses on the study and testing of a series of modular transport containers. The results are expected in 2020.

Standardized containerization is a subject that remains difficult because it involves significant investments to adapt logistics networks to these new tools. This approach is therefore gradual.

Perspectives

Current logistic organizations suffer from limitations related to network and flow fragmentation that leads to low efficiency at ever higher service levels. The organization promoted by the physical Internet, by the extent of the resources available and the flexibility of the routing, makes it possible to reach levels of efficiency that are very much superior from a theoretical point of view to the current organizations.

The partial experiments of the physical internet (containerization, monitoring, routing, etc.) carried out by companies, internally or at the level of groups of companies in a sector, have yielded convincing results. This means that it is not necessary to deploy all the elements of the physical internet to benefit from improvements in current operations. The fact that physical internet concepts can be used successfully by companies opens up interesting and potentially more accessible fields of application.

Experiments, ongoing operations and projects are yielding encouraging results. As such, the two next steps in the development of the Physical Internet can be envisaged within a few years. The first is to define a governance of the physical internet, in charge of collecting and synthesizing the results obtained, in order to turn them into technical and organizational recommendations. This step is fundamental to allow actors not involved in the developments to appropriate the results and to implement them. The European technological platform ALICE can play a major role at this level because it federates a large community of industrial and institutional players at the European level with two major objectives. The Physical Internet up and running in 2030 to reap gains from greater efficiency and zero emissions in 2050 to meet the objectives of sustainable development. The second step will be to extend to sectors other than that of fast-moving consumer goods that is currently at the cutting edge on this subject and to strengthen international collaboration around the Physical Internet.

Acknowledgment

The original development of the Physical Internet occurred during a set of workshops organized with Pr. Benoit Montreuil and Pr. Russell D. Meller. The authors also acknowledge the major role played by Sergio Barbarino from P&G and Fernando Liesa from the ALICE European Technology Platform in the development of the Physical Internet in Europe, with the strong and continuous financial support of the European Commission. Last but not least, the authors also want to sincerely thank all partners of the Chair Physical Internet (www.cip.mines-paristech.fr): P&G, GS1 France, FM Logistic, Carrefour Supply Chain, and Orange, for their trust, contributions, and financial support.

Challenges for Urban Freight

Urban traffic is characterized worldwide by high densities and overloading, causing congestion as well as environmental harm such as air pollution and noise. Congestion is not only due to the use of the individual car, but also to commercial road transport that constitutes between 25% and 35% of the overall urban traffic in the cities of the industrialized world (Menge and Horn, 2014), thus contributing significantly to total urban transport emissions; A quarter of CO₂ emissions, a third of NO_x emissions and half of particulate matter emissions (Dabanc and Rodrigue, 2017). Urban freight has been increasing continuously during the last decade, with a particular growth in the number of parcel deliveries that constitute by far the largest share of urban deliveries. In Germany, for instance, the number of parcel deliveries in 2018 was about 3.5 billion (based on BIEK, 2019), in the UK it was 3.65 billion in the same year (Mintel, 2019), in France, 1.6 billion (Ecommerce News, 2019). Besides an increase in vehicles circulating on the streets, the growing amount of freight deliveries also generates obstacles as delivery vehicles are standing on the street and impair the traffic flow.

Against this background, the EU has set an ambitious goal for urban freight: in 2011 the Commission declared to “achieve essentially CO₂-free city logistics in major urban centers by 2030” (European Commission, 2011). Solutions to reduce CO₂ emissions and other environmental harm of urban freight deliveries are the optimization of delivery operations, new delivery options (for instance, pickup locations with parcel lockers) or the use of environment-friendly vehicles like electric vans or cargo bikes. There is no standard solution, but projects and “real-life” application of cargo bike delivery have shown that concepts fulfilling both the requirements of freight service providers and the expectations of cities are manageable by case-specific adaptations.

In addition, cargo bikes may not only be used for logistics services in the urban context, but also for internal, on-site transport of firms, for service trips or the transport of materials and tools that, for instance, a craftsman or a chimney sweep needs for his or her work, or for private purposes to transport errands (or children). This article, however, will focus on bicycles for urban freight in the logistics sector.

Urban Freight and Urban Deliveries—Characteristics and Volumes

There is no general definition for urban freight. As stated by Behrends et al. (2008), different perspectives may be applied to define “urban freight”—location, actors, or products. They use a definition that focuses on the combination of goods and their receivers, but also includes locational aspects, and suggest the following list:

- provision of industry with raw materials and semi-manufactured articles;
- provision of the wholesale trade with consumer goods;
- provision of shops with consumer goods;
- inbound and outbound consumer goods produced in the area;
- home deliveries made by professional delivery operators; and
- transit transport of goods.

There exists hardly any data about the shares in urban freight of different categories of goods. Rough estimations by Sonntag (2015), however, indicate for the year 2010 that a share of 38% of all truck trips in urban commercial transport in Germany have been carried out by courier, express and parcel (CEP) services. This is followed by an 18% share for wholesale and retail logistics, 15% freight forwarding/general cargo, 14% construction and building craft, 10% specialists’ trips, and 5% provision from industry and manufacturing.

Table 1 CEP volumes in German cities in 2016

	<i>Regional level</i>	<i>CEP deliveries (million) in 2016</i>	<i>Share of all German CEP deliveries</i>	<i>CEP deliveries per year per inhabitant</i>
Germany	National	3,160	100.0 %	38
Bavaria	State (Bundesland)	540	17.1 %	42
Munich	City	89	2.8 %	61
Berlin	City	130	4.1 %	37
Hamburg	City	90	2.9 %	51
Stuttgart	City	37	1.2 %	60
Düsseldorf	City	36	1.2 %	59

Source: BIEK (2018b)

The list of goods in urban freight reveals that the total of “urban freight” incorporates a broad range of goods, including goods for which cargo bike transport would not make sense or even be possible, due to obvious restrictions in driving range, carrying capacity, or payload volume. Other “typical” goods for bicycle messengers, such as legal documents or tickets, are increasingly becoming digitalized. Nonetheless, there is still a large variety of feasible goods, such as spare parts, medical samples, fresh produce transported in small load carriers.

The CEP services market is a main field of application for bicycle logistics, as it is characterized by lightweight shipments. In Germany, the average weight of a CEP shipment was 7.4 kg in 2016 and the total annual transport volume of the CEP industry was 23.5 million tons (BIEK, 2018a), which is less than 1% of the total road freight transport in Germany. Nonetheless, looking again at the 38% share of all urban commercial truck trips caused by CEP services, the need for action becomes evident.

With this general focus on parcels as the main type of freight, delivery concepts that use bicycle transport can be divided into four major groups:

1. Point-to-point/courier shipments
2. Express parcel deliveries (via microhub)
3. Home deliveries (e.g., grocery box, cooked meal)
4. Own-account/internal freight transport.

Cities are typically the top priority of CEP services. These markets have considerably changed during the last decade, above all by the huge increase in parcel deliveries to households, that is, B2C deliveries (business to consumer). The main driver has been online shopping for which cities are hot spots: The per capita delivery in German cities is far above the national or state average (Table 1). In Munich (capital of the German state of Bavaria), for instance, the per capita number is 61 while it is “only” 42 for Bavaria and 38 as the national German average (BIEK, 2018b). This underlines the particular challenge for alternative solutions in the urban delivery sector.

The Technical Evolution of the Cargo Bike

Due to EU regulation, cargo bikes commonly used for urban freight transport are legally equal to “conventional” bicycles (with all rights and obligations) as long as they do not exceed a pedal-assist engine of 250 W and an assisted speed of 25 kph (European Commission, 2020). Besides this legal classification, however, cargo bikes are certainly “more” than just bicycles. Other than a conventional bicycle, they offer transport possibilities by fixed cargo boxes, flexible containers or open cargo platforms of different sizes and different shapes. Dozens of construction types of cargo bikes exist: there are cargo bikes with 2, 3, 4, or even more wheels, diverse locations of the cargo and ways of steering. Information on the five main cargo bike construction types, as well as bicycle trailers can be found in Table 2.

The use of cargo bikes to transport goods has a long history. By the end of the 19th century, the high wheel with two wheels—a vehicle that was quite difficult to handle—was developed into a more robust three-wheel vehicle that offered new options for freight transport (Dodge, 2011; Rauck et al., 1979). In the beginning of the 20th century, the “Long John bike” was developed in Denmark. Cargo bikes were commonly used for home deliveries of milk or other goods and specific cargo bikes were developed for several purposes, for instance for postal services or for ambulance services. Due to the spread of automobiles, cargo bikes became nearly extinct for freight transport in the second half of the 20th century and were predominantly used for private mobility in some cities such as Copenhagen.

The recent development of cargo bikes has focused on the extension of transport weight and volumes, the comfort of the driver, but most importantly on new propulsion systems. The growing demand for conventional e-bikes (electrically-assisted bicycles) led to the development of powerful and reliable electric engines and flexible battery systems. This can be seen as one key factor for the renaissance of commercially applicable cargo bikes, together with a change of awareness toward the negative externalities of rapidly increasing urban freight trips. One of the most recent innovations to improve the propulsion of cargo bikes is H₂/fuel cell technology

Table 2 Characterization of typical construction types of cargo bikes

No. of wheels	Construction type	Side view	Payload volume	Carrying capacity Q1–Q3 range ^a	Vehicle characterization, driving behavior, features and typical transport tasks
2	Pizza delivery bike		90 L (back) + 40 L (front)	50–79 kg (n = 17)	- One track vehicle similar to conventional bicycles concerning frame and driving behavior - High cargo areas above front wheel and rear wheel - Feasible for small transports covering all trip distances
2	Long John bike		150–300 L	80–100 kg (n = 23)	- One track vehicle with extended wheelbase and low cargo area in front of the driver - Indirect steering of the smaller front wheel by thrust rod or cable pull - Longer but not necessarily wider than a conventional bicycle, unusual driving behavior - For fast light/medium-weight transports covering all trip distances
2	Longtail bike		Typically open platform (no closed cargo box)	70–105 kg (n = 8)	- One track vehicle with extended wheelbase and cargo area behind the driver - No sight obstruction even when transporting bulkier goods - Longer but not necessarily wider than a conventional bicycle, familiar driving behavior - For fast light/medium-weight transports covering all trip distances
3	Tricycle, front load		330 L	80–120 kg (n = 44)	- Two track vehicle with low cargo area in front of the driver - Wider than conventional bicycles - Traditional models with turntable steering: tip-over protection only whilst standing, no fast turns possible; for less time-critical medium-weight transports or multi-stop deliveries covering short and medium trip distances - Models with Ackerman steering (tilting technology: Considerably more agile and faster turning velocities; feasible for long distances, too)
3 (4)	Heavy-load tri-cycle (quadricycle)		1300–2300 L	125–200 kg (n = 27)	- Two track vehicle with cargo area behind the driver for high payloads, usually compatible with EPAL pallets - Tip-over protection whilst standing, slow operative velocities; for large and heavy-weight transports of 100 kg or more - Some models include weather protection covers
2-3	Bicycle trailer		1300–1700 L or open platform	(around 150 kg)	- Trailers are compatible with most conventional bicycles and cargo bikes with single rear wheel - Some models include electric assist of up to 25 kph while towing as well as up to 6 kph when operated as handcart using the trailer's drawbar

^aCarrying capacity: Based on a market research by Schenk et al. (2017) including carrying capacity information of 121 cargo bike models. Stated is the range between first and third quartile and the number of models.

Source: Own representation based on Behrensen and Gruber (2017) and Schenk et al. (2017).

that can provide a higher energy density than batteries. Furthermore, the hydrogen tank can be refueled within seconds and suffers no performance loss at low temperatures (DLR, 2020).

In the last decade, many cargo bikes have become available that allow for payloads far beyond the 25 kg of standard bikes, thus significantly opening up the potential range of tasks, and cargo bikes have started to satisfy the rising demand for city center point-to-point small-scale consignment delivery. Today's cargo bikes can operate 100–200 kg of total carrying capacity and up to two cubic meters of payload volume; they may have a container designed for the transport of a standard EPAL pallet. This significant increase in options and performance fostered the integration of cargo bikes into urban delivery concepts. Carrying capacity needs to be checked in accordance with the permissible gross vehicle weight, which also includes weight of the vehicle and its driver. Although a few cargo bikes may allow for loads up to 500 kg, their main purpose is to deliver parcels that have a weight of up to 31.5 kg and a maximum size of $120 \times 60 \times 60$ cm, but far less in most of the cases, as bicycles are operated by individual persons without assisting lifting devices. According to the German bicycle industry association ZIV, the amount of electric cargo bikes sold in Germany has risen from 10,700 in 2015 (there is no earlier data) to 39,200 in 2018 (ZIV, 2019).

The Development of Cycle Logistics and New Delivery Concepts

In Germany, the 1990s saw a peak in the foundation of bicycle courier companies providing immediate and fast point-to-point courier deliveries in the denser urban context. Most of these conventional business models were the provision of a platform to organize the interface between demand and individual couriers operating with a bicycle and a backpack. While the use of human-powered bicycles and cargo bikes will most likely remain limited to the courier market, the abovementioned electrification, as well as diversification of cargo bike models, allowed for an expansion of cycle logistics.

The use of cargo bikes for parcel shipments is often embedded in new delivery concepts that aim at reducing the environmental impact of urban freight and improving urban traffic flows, while simultaneously decreasing the cost for delivery service providers. An integral part of these concepts are urban distribution centers (micro-depots, microconsolidation centers, city cross docks). They are regarded as the central element of the new urban logistics concepts (Conway et al., 2011; Dablanc, 2011; Koning and Conway, 2014; Lenz and Riehle, 2013). Freight is carried to micro depots by larger motorized vehicles and then redistributed to smaller vehicles that provide a more environment-friendly distribution than conventional vehicles do. These small distribution centers are located close to, or even within, the inner city and may be installed as either permanent infrastructure (CityLog, 2012) or mobile infrastructure that allows for flexibility on a daily basis. Mobile depots are mostly containers or truck trailers that are located in designated areas (Verlinde et al., 2014).

Depending on the specific urban context in which the new concept is applied, it may also be combined with modes other than the truck to fill (or bring from) the depot; examples exist for the combination of ship and cargo bikes in central Paris (Hotel logistique Porte de la Chapelle). For the final 50 feet of the logistics chain, other low emission vehicles may be used as an alternative to cargo bikes, as for instance hand trucks that are used for the very short distances from curbside to the receiver or within the receiver's building (cf. University of Washington, 2020).

Besides point-to-point courier shipments and parcel shipments via microdepot, bicycles are often used for meal delivery or retail home delivery, both by large retail chains and niche providers (such as shippers of regionally grown fresh produce). Some "brick and mortar" stores started to collaborate and enter hybrid distribution channels by offering online order and emission-free last-mile delivery by a shared cargo bike.

The strengths and weaknesses of cargo bikes might also be seen as connected to the re-urbanisation of logistics areas (e.g., by Amazon's urban hubs) and the creation of more flexible delivery options, such as same day delivery or instant delivery (within the next 2 h). Cargo bikes are often implemented as parts of these concepts as they are less sensitive to congestion in the city centers. The most challenging element for these concepts is the cost decrease: Depending on the type of cargo bike and the type of conventional delivery vehicle, the payload volume of the conventional last-mile delivery vehicle is equal to 15–20 cargo bikes. This means that the switch to a concept which uses cargo bikes for a direct substitution of conventional delivery vehicles requires either more vehicles and drivers or a broader time window for deliveries (Raiber, 2015). From a business-economic perspective, the marginal transport costs for bikes today are higher than those of light commercial vehicles (€4.61 vs. €3.40 per stop), mostly due to higher labor costs. Using a welfare-economic viewpoint including the external costs (e.g., for emissions, noise and accidents), the balance is reversed and the marginal costs for bike deliveries would be lower than those of conventional vehicles (€4.52 vs. €6.05) (Maes, 2017). Another estimation looks at the cost parameters of cargo bikes for instant deliveries using a micro-depot and finds them economically viable compared to conventional approaches (Rudolph et al., 2018). It is obvious that business models implementing bicycles are part of dynamic markets both with expanding businesses, but also failures. In 2019, for instance, both Foodora and Deliveroo withdrew from the German meal delivery market (Fig. 1).

Infrastructure for Bicycle Freight

Cargo cycles have similar infrastructural demands as private bicycle transport, but there are some particularities (Conway et al., 2011; Gruber and Rudolph, 2016):

Figure 1 Comparison of payload volumes and carrying capacities of conventional vehicles and cargo bikes. *Source:* Own representation, based on Raiber (2015).

- As transporting goods is usually time-sensitive, cargo bikes often run at relatively high velocities.
- Broader spectrum of velocities.
- Larger cargo cycles need more space for parking.
- Heavy loaded cargo cycles have longer braking distances and larger turning radii.
- Higher vulnerability regarding slopes, steps and vibrations.

In addition, the implementation of cargo cycle concepts has specific requirements concerning the availability of inner-urban spaces and the design and usability of the urban (road) space (Conway et al., 2011; Gruber and Rudolph, 2016):

- There must be enough space to put up depots; this space needs to be permanently assigned for the new logistics concept, at least on weekdays.
- The depots—if permanent or mobile—must be accessible for trucks that deliver the freight.
- Ramps for cargo bikes must be provided to protect them from weather effects and vandalism.
- In case of electric cargo bikes loading infrastructure is needed (Raiber, 2015).
- Planning manuals for roads design should enclose the dimensions of cargo cycles.
- State-of-the-art infrastructure is needed.
- Redesigning the complete bicycle infrastructure of cities is neither possible nor necessary, also small constructive adjustments may have high impacts.
- Using cargo cycles should be legal on all urban roads.

Experiences from Projects and Practical Examples

In Germany, 800 companies and public institutions participated in a large-scale cargo bike testing scheme (project “Ich entlaste Städte”) with a total operative mileage of approximately 300,000 km. Without cargo bikes, two out of three of these kms would have

been conducted with a combustion engine vehicle. Around 30% of the testers acquired their own cargo bike after the trial. The project was particularly popular among self-employed persons, freelancers and small companies providing deliveries or services.

In the city of Hamburg, a CEP service provider (UPS) operates four microdepots to service the inner city area by cargo bike and handcarts. In the morning and in the evening, a truck trailer with parcels is brought to, or picked-up at, each microdepot location. An evaluation showed that 4–6 conventional 7.5 t delivery vehicles are substituted by 7 heavy-duty trikes, 4 front-load trikes and a number of handcarts. The before-after assessment of emissions showed a decrease from 25–30 t to 11 t of CO₂ and a decrease from 85–101 kg to 39 kg of NO_x (Ninnemann et al., 2017). UPS themselves state a commercially viable substitution of up to 10 conventional delivery vehicles by the ongoing concept. In Berlin, several parcel service providers participated in the project “KoMoDo”. While there was no company-overarching consolidation of shipments, it can still be viewed as one of the first examples where competing parcel companies collaborated under the roof of a municipal operator, in this case the Berlin freight port operator Behala.

A study on the use of heavy-duty bikes at two CEP services (DPD and GLS) in Nuremberg found an economically viable substitution of seven conventional delivery vehicles by eight cargo bikes, saving around a quarter of greenhouse gas and air pollutants. To this end, the authors carried out a micro-simulation with cargo bikes as part of a microdepot concept based on data of the current state, that is, conventional parcel delivery. On the basis of unspecified internal calculations, the authors indicate a potential shift from fuel-based vehicle to cargo bike of 30% of the total CEP deliveries in cities with over 100,000 inhabitants (Bogdanski et al., 2017).

The Potential of Bicycles for Urban Freight

As it was expressed earlier, cargo bikes are not the solution for urban freight in general, but rather for specific purposes within the urban context. Assessments concerning the potential of substitution for conventional vehicle use and, thus, the environmental effects of cargo bike use display considerable differences in their results. Most studies are based on the number of trips and kilometers driven per trip that currently are made by motorized vehicles (motorcycles, cars and light duty vehicles up to 3.5 t) compared to what can be substituted by cargo bikes.

Studies that take into account broader market segments of cargo bike use estimate that the overall substitution rate of cargo bikes for motorized vehicles will be between 8% and 23% of trips and between 1% and 4% of the mileage. Besides the influence of the share of electrification in the cargo bike fleet on the total substitution, a major factor is the readiness of drivers and companies to use cargo bikes and—directly related to this—to restructure logistics operations (Gruber and Rudolph, 2016). Although it may seem that the low share of mileage that can be substituted will not be relevant to reduce environmental harm in cities, these reductions occur in particular in inner city areas and in residential areas and thus are absolutely relevant on a local scale.

Studies that consider specific market segments, single courier companies (Gruber et al., 2014) or smaller areas inside the inner city (CityLog, 2012) result in much higher substitution potential. Other studies that show high potential of more than 50% of substitution consider all privately and commercially motivated transport of goods (Cyclelogistics, 2014).

Outlook

Cargo bicycles will play an increasingly important role in urban logistics. A major driver will be the cities' growing demands on environmentally friendly logistics, which logistics service providers will have to take into account in the future. In view of a European context in which the environmental impact of (urban) delivery traffic is more and more being considered by EU legislation, efforts to innovate are increasing, both in the technological development of cargo bikes and in the implementation of new concepts. The introduction of new framework conditions for inner-city traffic and the use of vehicles that are powered by fossil fuel could result in additional incentives for the use of cargo bicycles.

Introduction

Chinese President Xi Jinping announced the Silk Road Economic Belt (SREB) on September 7, 2013, in Astana, Kazakhstan, and the 21st century Maritime Silk Road (MSR) Initiative on October 3, 2013, in Jakarta, Indonesia. Initially, they were together called “One Belt and One Road (OBOR).” However, the Chinese government officially changed it to the “Belt and Road (B&R)” on September 24, 2015.^a Its more concrete contents and directions have been addressed in the *Vision and Actions on Jointly Building Silk Road Economic Belt and 21st-Century Maritime Silk Road* published on March 28, 2015 (NDRC, 2015), hereinafter referred to as the “BRI document.” As of April 30, 2019, China has signed 187 cooperation agreements on the BRI with 131 countries and 30 international organizations since its inception in 2013.

The BRI document consists of the MSR and the SREB. The former is designed to go from China’s coast to Europe through the South China Sea and the Indian Ocean on one route, and from China’s coast through the South China Sea to the South Pacific in the other. The latter focuses on railways and highways connecting China to Central Asia, Russia, and Europe (the Baltic). Therefore, the BRI aims to “promote the connectivity of Asian, European and African continents and their adjacent seas, establish and strengthen partnerships among the countries along the B&R, set up omni-dimensional, multi-tiered and composite connectivity networks, and realize diversified, independent, balanced and sustainable development in these countries” (NDRC, 2015, p. 2). The BRI document consists of a preface and eight chapters comprising (1) Background, (2) Principles, (3) Framework, (4) Cooperation Priorities, (5) Cooperation Mechanisms, (6) China’s Region in Pursuing Opening-Up, (7) China in Action, and (8) Embracing a Brighter Future Together. Some key words in the BRI document are, among others, China’s inland region, connectivity, economic corridor, transport corridor, city cluster, pilot free trade zone, marine economy development demonstration zone, marine economy pilot zone, core area, bay area, infrastructure, and financial mechanism (Lee et al., 2018a). This article will introduce China’s BRI, focusing on transportation connectivity and infrastructure.

Economic and Transport Corridors in the BRI

There are three ways to connect China to Europe, that is, (1) MSR, which is partly the same as the existing southwest bound maritime routes, (2) SREB, which is mostly the same as the existing rail routes via the Trans-China Railway (TCR) and the Trans-Siberian Railway (TSR), and (3) the Polar Silk Road (PSR). Recognizing China’s interest in developing Arctic shipping routes, in January 2018 the Chinese government announced a white paper on “China’s Arctic Policy” to establish a comprehensive B&R as the “three Silk Roads,” referring to the joint promotion of land (Belt), sea (Road), and the Arctic (Fig. 1).

Figs. 2 and 3 provide a summary of the economic and transport corridors outlined in the BRI document.^b These are as follows:

- China-Pakistan Economic Corridor (CPEC): Kashgar (Xinjiang Uygur autonomous region)—Gwadar port (Pakistan).

^a The Chinese government also announced that strategy, project, program, and agenda should not replace “initiative” (<http://news.sina.com.cn/c/sz/2015-09-24/doc-ifxhzevf1026412.shtml>).

^b Recently, Chinese Belt and Road Portal (2019) designates six international economic cooperation corridors, namely, (1) the New Eurasian Land Bridge, (2) the China-Mongolia-Russia Economic Corridor, (3) the China-Central Asia-West Asia Economic Corridor, (4) the China-Indochina Peninsula Economic Corridor, (5) the China-Pakistan Economic Corridor, and (6) the Bangladesh-China-India-Myanmar Economic Corridor (<https://eng.yidaiyilu.gov.cn/qywx/rdxw/88408.htm>).

Figure 1 Connecting China to the rest of the world. Note: The width of the pink color indicates the amount of ship traffic flows. Source: Modified by the author based on Lee et al. (2016).

Figure 2 Summary of corridors in the Belt and Road (B&R). Source: Lee (2016).

- Bangladesh-China-India-Myanmar Economic Corridor: Kunming (Yunnan province, China)—Mandalay (Myanmar)—Dhaka (Bangladesh)—Kolkata (India).
- Four sub-corridors in Greater Mekong Subregion Economic Cooperation (GMSEC).
- China, Mongolia, and Russia Economic (CMR) Corridor: Heilongjiang Silk Road Belt.
- Beijing–Moscow Eurasian high-speed transport corridor: Beijing (China)—Khabarovsk (Russia)—Irkutsk (Russia)—Yekaterinburg (Russia)—Moscow (Russia)—Astara (Azerbaijan).
- Lanzhou–Kathmandu South Asia Freight Rail (LKSAFR).

Figure 3 Beijing–Moscow Eurasian high-speed transport corridor. Source: Lee (2016).

The expected impacts of the corridors are multidimensional and include, but are not limited to, a change of energy supply chain, Chinese global port chain development, dry port development in inland China, inter-port competition, infrastructure development, and so on (Lam et al., 2018; Lee et al., 2018a; Wei et al., 2018; Chen et al., 2019). Out of the earlier six corridors, CPEC is expected to play a key role in generating port regionalization and network reconfiguration across the ports in the Indian Ocean. This is because Hambantota Port in Sri Lanka has been leased to China for 99 years, in tandem with the development of Colombo port in Sri Lanka and Gwadar Port in Pakistan within the context of the BRI (Lee et al. 2018a; Ruan et al., 2019). The planned 18 billion US dollars investment for building the CPEC includes the Karot hydropower project, which is the first project of the Silk Road Fund (SRF). In addition, the CMR economic corridor (the so-called Heilongjiang Silk Road Belt) is interrelated to Korea's "New Northward Policy," Russia's "New East Asian Policy," and the maritime logistics connectivity of ports and shipping networks in the East Sea Economic Rim within the context of the BRI, in which the development of trade transit transport corridors is critical in the northeast Asian region (Lim et al., 2017). All the aforementioned are interwoven within the BRI context in the northeast Asian region.

Ports/Terminals Invested in by Chinese Stakeholders Under the "Going Global Strategy"

China's seaports play a key role in connecting China to the rest of the world along the MSR. Therefore, President Xi Jinping has described a port as an "important pivot point" and an "important hub" on a number of occasions in international fora in order to highlight their importance. In addition, China claims the BRI as a growth enabler in the world economy, in association with transport infrastructure. Data from the Ministry of Commerce show that Chinese enterprises invested a total of 14.53 billion US dollars in countries along the B&R in 2016. As of the end of 2016, Chinese enterprises set up 56 inchoate cooperation zones in countries along the B&R, with an accumulated investment totaling 18.55 billion US dollars.

Fig. 4 shows 15 coastal city developments along the Chinese coastline. The coastal cities are Shanghai, Tianjin, Ningbo-Zhoushan, Guangzhou, Shenzhen, Zhanjiang, Shantou, Qingdao, Yantai, Dalian, Fuzhou, Xiamen, Quanzhou, Haikou, and Sanya. The 15 ports try to actively promote the "Going Global Strategy" (GGS), and to respond to China's BRI by becoming key gateways (Fig. 1). They are connected by two major hub airports, that is, Shanghai and Guangzhou. This strategy aims to connect China to the rest of the world by strengthening the functions of their international hub airports and by developing the two airports for efficient hub-and-spoke operations with the coastal cities.

The GGS is being implemented by three players in China, that is, COSCO Shipping and Ports, China Merchants Group, and Chinese local port groups. Tables 1–3 show the foreign ports/terminals in which these three players have invested in along the MSR since the inception of the BRI in 2013. Most of the ports/terminals have been acquired by them through acquisition and public-private partnership (PPP).

The Polar Silk Road (PSR)

The Chinese government has announced *China's Arctic Policy* in January 2018 (State Council Information Office of the People's Republic of China, 2018), in which the PSR is similar to Arctic shipping routes comprising the Northeast Passage, the Northwest Passage, and the Central Passage. The document has the following contents:

- The Arctic situation and recent changes,
- China and the Arctic, and
- China's policy goals and basic principles on the Arctic.

As a result of global warming, the PSR is likely to become an important transport route for international trade. China's policies and positions on participating in the PSR are described as follows:

- Deepening the exploration and understanding of the Arctic,
- Protecting the eco-environment of the Arctic and addressing climate change,
- Utilizing Arctic resources in a lawful and rational manner,
- Participating actively in Arctic governance and international cooperation, and
- Promoting peace and stability in the Arctic.

Therefore, there are three ways available for China to be connected to Europe, that is, the existing southwest bound maritime routes, railway by TCR and TSR, and the PSR. China's interest in developing the PSR arises from her desire to establish a comprehensive B&R utilizing the "three Silk Roads," that refer to the joint promotion of land (One Belt), sea (One Road), and the Arctic (PSR).

Transport Infrastructure Projects in the BRI

Table 4 shows a summary of BRI projects between January 2013 and March 2019. Since its inception in 2013, the BRI has triggered 695 projects in 98 countries. 142 projects of these projects have been completed, 265 projects are under construction, 250 projects are under contract, 14 have been suspended and/or cancelled, and 24 projects are merely signed Memorandum of Understandings (MoUs).

Table 5 shows that out of the 695 projects in 98 countries, 597 projects can be classified as infrastructure projects. Among those, 217 projects are related to transport infrastructure, comprising 32 seaport/terminal projects, 16 airport projects, and 42 railway projects.

Table 4 Summary of BRI projects as of March 2019

Status	Number of project
Completed	142
Contract	250
MOU	24
Suspension/cancellation	14
Under construction	265
Total	695

Shipping cost (USD/FEU)		1500 USD/FEU (A.P. Moller-Maersk A/S (MSK)'s freight)			
Total costs (USD/FEU)	2145	2626	1943	1758	1500

Source: [Jiang \(2018\)](#).

Connecting China to Europe by Railway

As discussed in the previous section, there are three possible routes to connect China to Europe. [Fig. 1](#) shows the existing shipping route, the rail routes via the TCR and TSR, and the Arctic shipping routes (the so-called PSR). The current shipping routes have been well established for logistics providers and carriers for China. The discussion on the railway mode to connect China and Europe requires a prerequisite assumption that the capacity of the railway and demand for the service are to be justified and that modal competition between the railway service and the shipping service in terms of freight and service quality is acceptable. The China-Europe freight rail service network, in the form of the SREB, has connected China with 50 cities in 15 European countries, thanks to the existing TCR. As of February 2019, the total freight rail service reached 14,000 trips. [Table 6](#) shows the five major routes connecting China to Europe, highlighting the comparative data on freight time and cost between the railway service and the shipping service. It should be mentioned that some rail routes are subsidized by Chinese central and regional governments.

[Table 6](#) shows that China has five main railway service routes for Europe by origin city that use an intermodal service. They have a weekly service, with each block train having more than 42 wagons. Their total freight costs range from 1500 to 2626 US\$ per forty-foot equivalent unit container (FEU). The highest freight rate 2626 US\$/FEU by intermodal service is still higher than the lowest railway freight, while the former's total transportation time is longer than the latter's. Apparently, from the viewpoint of the overall aspects of freight cost and service period between China and Europe, the Chinese railway service is more competitive than the shipping service, thanks to the subsidies received from central and local governments. As can be seen in [Fig. 1](#), if all corridors are working well in the future, the size of the hinterland in the green circle would be encroaching upon those of Shanghai and Ningbo Ports ([Lee et al., 2018a](#)). As a result, this would cause more severe inter-port competition between Shanghai and Busan Port to capture transshipment cargoes with price competition ([Anderson et al., 2008](#)).

China has made an effort to establish dry ports in Europe for enhancing the efficient connectivity of railway services between China and Europe. [Fig. 5](#) shows a development strategy to connect China to Europe by establishing a distribution center, the so-called "Great Stone" industrial park of 95 km², in Minsk in Belarus.^c This was invested in by the China Merchants Group and is

^cThis is based on the author's field trip to Lithuania with meetings and interviews on October 7–11, 2018: meetings with Vice Minister of Transportation, Lithuania; Director of Klaipeda port and CEO of Free Trade Zone (FTZ); CEO of Kaunas FTZ; interviews with China Merchants Groups from Minsk, Belarus; and Secretary-General of China International Freight Forwarders Association.

Figure 5 Connecting to China to Europe by railway. Source: Lee (2018).

adjacent to Lithuania, Germany, and Poland. This center aims to provide a distribution service for cargoes coming from China by railway, as well as to accommodate block trains. The characteristics and advantages of the location are as follows:

- A block train service is available between China and Belarus (e.g., Changsha-Great Stone Park).
- The gauge of the Lithuanian rail system is the same as Russia, China, and other CIS countries, so that the railway operator does not need to change the bogie system of the wagons.
- The border crossing time between Lithuania and the Great Stone industrial park in Minsk, Belarus takes 30 minutes for one block train; this is the so-called “Shuttle train Viking.”
- Lithuania offers a free economic zone in Klaipėda and Kaunas ports, with tax incentive policies to attract cargoes from China. Once the cargoes complete customs clearance in the country, they do not need any more customs clearance within the EU market because the country is a member of EU.
- Klaipėda Port expansion by CMG is under negotiation with an MoU.
- Port infrastructure is provided by central government and the superstructure by terminal operators.
- Major shipping lines are calling at Klaipėda, for example, MSC and Yang Ming. COSCO is planning to do the same, subject to China Merchant Groups’ investment decision.
- Minsk is expected to capture cargoes to and from the Scandinavia Peninsula through Klaipėda Port.

Despite the earlier advantages, China’s block train cannot be commercialized for Lithuania because Russia charges 3–4 times more than the normal usage rate of Russian railways for the direct block trains bound for Lithuania from China.

Having recognized the earlier merits and strategic location of Minsk, Lithuania has set up a global logistics hub strategy in the Baltic Region which aims to not only connect China by railway and seaport to Lithuania through the Great Stone industrial park in association with free economic zones in Klaipėda and Kaunas, but also capture cargoes to and from Western Europe and the Scandinavian countries. Therefore, the two countries are together trying to solve the higher usage rate issue of the Russian railway section, because both can get benefits from the direct block train services. This is an example of why governments are motivated to intervene to remove obstacles to the implementation of the BRI (Lee et al., 2018b).

The earlier Lithuania-China case also gives Chinese stakeholders a couple of insights. First, the rail operator in collaboration with logistics providers needs to consider expanding a strategic distribution center in Europe. For example, Klaipėda and dry ports in Lithuania could provide an alternative as the final rail terminus for rail freight movements from China Asia to Europe, instead of Duisburg. This is partly because the whole service from Northeast Asia to Lithuania has the same railway system and partly because Lithuania is an EU member. Last, but not least, the cargo imbalance between China and Europe should be considered. Klaipėda Port has signed an (MoU) on constructing container terminals with China Merchants Group. This may help mitigate the imbalance issue in association with Chinese shipping companies which try to capture cargoes to and from the Baltic and Scandinavian regions and to trigger inter-port competition with Gdansk Port.

Developing City Clustering and Restructuring the Transport System Through the BRI

One of the purposes of the Chinese BRI is to try to promote city clustering (Fig. 6) and introduce more advanced “pilot” free trade zone and big bay area (Fig. 7). The BRI designates the following in this respect: (1) Yangtze River City Cluster,

Figure 6 City clustering in the BRI. Source: Lee (2016).

Figure 7 Introducing pilot free trade zones and big bay areas into the BRI. Source: Lee (2016).

(2) Chengdu-Chongqing City Cluster, (3) Central Henan City Cluster, (4) Hohhot, Bator, Erdos, and Yulin City Cluster, and (5) Harbin-Changchun Metropolitan Area Cluster.

This clustering development aims to:

- set up coordination mechanisms in terms of railway transport and port customs clearance for the China-Europe corridor;
- cultivate the brand of “China-Europe freight trains”;
- construct a cross-border transport corridor connecting the eastern, central, and western regions;
- support inland cities such as Zhengzhou in building airports and international land ports (= dry ports);
- strengthen customs clearance cooperation between inland ports (= dry ports) and ports in the coastal and border regions; and
- launch pilot e-commerce services for cross-border trade.

The Asian Infrastructure Investment Bank (AIIB) and Funding for the BRI

The Asian Infrastructure Investment Bank (AIIB) was launched in January 2016 after 57 countries had signed its charter. The purpose of the AIIB is to foster sustainable economic development, create wealth, and improve infrastructure connectivity in Asia by investing in infrastructure and other productive sectors and to promote regional cooperation and partnership in addressing development

challenges, by working in close collaboration with other multilateral and bilateral development institutions (AIIB Article 1). Its paid capital is 100 billion US dollars. The BRI requires huge investment to construct infrastructure along the B&R (Table 5). Therefore, China has made efforts to establish financial integration as an important underpinning for implementing the BRI, so that China is able to establish a currency stability system, an investment and financing system, and a credit information system in Asia and to maintain the scope and scale of bilateral currency swaps and settlements with other countries along the B&R. The following additional funding sources are available for the BRI:

- Silk Road Fund
- BRICS New Development Bank
- Shanghai Cooperation Organization (SCO) financing institution
- Practical cooperation of China-ASEAN Interbank Association and SCO Interbank Association
- Multilateral financial cooperation in the form of syndicated loans and bank credit
- Bonds issues in both Renminbi and foreign currencies outside China by Qualified Chinese financial institutions and companies
- Bond market in Asia

The AIIB has two main group memberships, that is, “Members” and “Prospective Members.” Each group has regional and non-regional members, respectively. As of June 2019, the Bank has 70 members and 27 prospective members, totaling 97 members worldwide. Tables 7 and 8 show the top 10 regional and non-regional members of the AIIB and their shares and voting power. The top 10 regional members own 63.76 billion US dollars out of 96.4 billion US dollars of the total paid capital of the AIIB, equivalent to 58.3% of the voting power of all the AIIB members, while non-regional members have 22.5 billion US dollars, equivalent to 25.4% of the voting power of the total AIIB. China as a regional member owns the highest share ratio of 29.78%, while Germany as a non-regional member has the highest share of 4.65% of the total non-regional shares.

The BRI has been promoted by multilateral cooperation mechanisms under the Chinese strategy of making full use of existing mechanisms as follows:

- Shanghai Cooperation Organization (SCO),
- ASEAN Plus China (10 + 1),
- Asia-Pacific Economic Cooperation (APEC),
- Asia-Europe Meeting (ASEM),
- Asia Cooperation Dialogue (ACD),
- Conference on Interaction and Confidence-Building Measures in Asia (CICA),
- China-Arab States Cooperation Forum (CASCF),
- China-Gulf Cooperation Council Strategic Dialogue,
- Greater Mekong Subregion (GMS) Economic Cooperation, and
- Central Asia Regional Economic Cooperation (CAREC).

Table 7 Regional members and their shares and voting power of the AIIB

Rank	Regional members	Membership date	Total subscriptions: amount in million USD (% of total)	Voting power: number of votes (% of total)
1	China	December 25, 2015	29,780.4 (30.8913%)	300,338 (26.6167%)
2	India	January 11, 2016	8,367.3 (8.6794%)	86,207 (7.6399%)
3	Russia	December 28, 2015	6,536.2 (6.7800%)	67,896 (6.0171%)
4	Korea	December 25, 2015	3,738.7 (3.8782%)	39,921 (3.5379%)
5	Australia	December 25, 2015	3,691.2 (3.8289%)	39,446 (3.4958%)
6	Indonesia	January 14, 2016	3,360.7 (3.4861%)	36,141 (3.2029%)
7	Turkey	January 15, 2016	2,609.9 (2.7073%)	28,633 (2.5375%)
8	Saudi Arabia	February 19, 2016	2,544.6 (2.6395%)	27,980 (2.4797%)
9	Thailand	June 20, 2016	1,427.5 (1.4808%)	16,809 (1.4897%)
10	Iran	January 16, 2017	1,580.8 (1.6398%)	15,180 (1.3453%)
Subtotal (top 10 regional members)			63,637.3 (66.0113%)	658,551 (58.3625%)
Other regional members ^{a,b}			10,218.0 (10.5991%)	183,261 (16.241%)
Total (regional members)			Amount (million USD): 73,855.3	Number of votes: 841,812
			Percent of total: 76.6104%	Percent of total: 74.6035%
Grand total (total AIIB members)			Amount (million USD): 96,403.8	Number of votes: 1,128,381
			Percent of total: 100.0000%	Percent of total: 100.0000%

^aOther regional members include Afghanistan, Azerbaijan, Bahrain, Bangladesh, Brunei Darussalam, Cambodia, Cyprus, Fiji, Georgia, Hong Kong, China, Israel, Jordan, Kazakhstan, Kyrgyz Republic, Lao PDR, Malaysia, Maldives, Mongolia, Myanmar, Nepal, New Zealand, Oman, Pakistan, Philippines, Qatar, Samoa, Singapore, Sri Lanka, Tajikistan, Timor-Leste, United Arab Emirates, Uzbekistan, Vanuatu, and Vietnam.

^bKuwait was originally a regional member. The country's membership is currently under the category of prospective regional members as founding members of the prospective (Table 9).

China has been playing a constructive role in international fora and exhibitions at regional and subregional levels, hosted by countries along the B&R.

- Boao Forum for Asia
- China-ASEAN Expo
- China-Eurasia Expo
- Euro-Asia Economic Forum
- China International Fair for Investment and Trade
- China-South Asia Expo
- China-Arab States Expo
- Western China International Fair
- China-Russia Expo
- Qianhai Cooperation Forum
- Silk Road (Dunhuang) International Culture Expo
- Silk Road International Film Festival
- Silk Road International Book Fair

Concluding Remarks

The Belt and Road Initiative (BRI) has still a short history of 5 years, which may not be enough to observe its formidable outcome. However, it can be said that its impact on maritime transportation, trade, global logistics patterns, and railway service development between China and Europe are potentially large. In addition, the BRI has been carved into the General Program of the Constitution of the Communist Party of China at the 19th National Congress of the Communist Party of China on October 24, 2017, as follows: "The Party shall constantly work to develop good neighborly relations between China and its surrounding countries and work to

Figure 8 Proposed new Maritime Silk Road. Note: The blue dotted lines depict the MSR. A combined route with red dot lines is called the new MSR. Source: Lee (2016).

strengthen unity and cooperation between China and other developing countries. It shall follow the principle of achieving shared growth through discussion and collaboration, and pursue the *Belt and Road Initiative*." This implies that China has paved a solid path to the implementation of the BRI over the coming years.

Since the inception of the BRI in 2013, 131 countries and 30 international organizations have signed an MoU with China on the BRI. In this circumstance, not a few countries are facing two strategic options for the BRI: either a "Connect Strategy" or a "Being Connected Strategy." The former is proactive, while the latter passive. The freight rail network, with block train services between China and Europe, has diverted a certain amount cargo flow from sea transport to land transport. The PSR has been incorporated into the BRI since January 2018. Therefore, China's BRI has three ways of connecting China to Europe and the rest of the world.

In addition, China's three players, that is, COSCO Shipping Ports, China Merchants Group, and Chinese local port groups, have acquired overseas ports/terminals along the MSR through acquisition and PPIs under the "GGS." This is an interesting development for China in establishing a port supply chain along the MSR. On top of that, dry port development in Europe and in inland China has promoted China's freight rail services. Finally, China's engagements in the sub-Saharan region of Africa and in South America has led to proposal of a new MSR as shown in Fig. 8 (Lee et al., 2018a).

Acknowledgments

The author would like to express his thanks to Korea Maritime Institute for granting copyright permission for the use of his paper that appeared in the *KMI International Journal of Maritime Affairs and Fisheries* for this article.

Biography

Paul Tae-Woo Lee is currently Professor of Maritime Transport and Logistics and Director of Maritime Logistics and Free Trade Islands Research Centre at Ocean College, Zhejiang University in Zhoushan, China. He holds a PhD from Cardiff University in United Kingdom. He was also Visiting Scholar at, among others, Faculty of Economics and Politics in University of Cambridge in United Kingdom, University of Plymouth, Dalian University, Hong Kong Polytechnic University, Chulalongkorn University, the University of the Thai Chamber of Commerce, Shanghai Maritime University, and MPA Visiting Professor at Nanyang Technological University (Singapore). His research interests include maritime transport and logistics, and the Belt and Road Initiative (BRI) issues. He is also a regular speaker at international conferences, including the Asia-Pacific Economic Cooperation (APEC), United Nations Development Programme, UN Economic and Social Commission of Asia and the Pacific (ESCAP), ASEAN-Australia-New Zealand Free Trade Agreement, China Academy of Social Sciences (CASS), and Vietnam Academy for Social Sciences (VASS). In particular, since 2015, he was invited to international conferences, fora, and seminars on the BRI around the world as a well-known speaker. He has published 7 books and more than 300 journal and conference papers, and edited 28 special issues of distinguished international journals, including 10 issues regarding the BRI. He is currently Editor-in-Chief of *Journal of International Logistics and Trade*, and Associate Editor of *Transportation Research Part E* and *Journal of Shipping and Trade*, Book Editor of Elsevier's *China Transportation Series* and Book Editor of Anthem Book Series of *Supply Chain Management* and *Maritime Transport and Logistics*. He is a founding member of Yangtze River Innovation and

Research Belt (Y-RIB, 2018), BRI—International Collaboration Network (BRI-ICN, 2016), Asian Logistics Round Table (ALRT, 2007), and International Association of Maritime Economists (IAME, 1992). He served Co-opt Vice President and Secretary of IAME, including council members for more than 10 years. He is currently Permanent Secretary of the ALRT and Secretary of the BRI-ICN.

INTRODUCTION

Roger Vickerman

In an increasingly globalized world, despite reductions in costs and time, transportation has become even more important as a facilitator of economic and human interaction; this is reflected in technical advances in transportation systems, increasing interest in how transportation interacts with society and the need to provide novel approaches to understand its impacts. This has become particularly acute with the impact that Covid-19 has had on transportation across the world, at local, national, and international levels. This Encyclopedia brings a cross-cutting and integrated approach to all aspects of transportation from work in many disciplinary fields, engineering, operations research, economics, geography, and sociology to understand the changes taking place.

Transportation is both influenced by, and an influencer of, changes in the economy and society. Increasing speeds have reduced journey times and made the world a smaller place as globalization has affected both where people live and work and from where they source their goods and materials. Increasing volumes of traffic, often on old and life-expired infrastructure, lead to congestion and delays. Constraints on public budgets have led to increasing pressure on the private sector to fund improvements requiring new and innovative financial solutions. While there are clear differences in the nature of the pressures felt in the developed and less developed economies, there is an increasing recognition that in all societies, there is an accessibility problem such that certain groups become disadvantaged by the lack of access to reliable and cost-effective transport. While the problems are clearly multidimensional, research on transportation is often constrained by single disciplinary approaches and this carries over into the practice of transport planning and policy. The Encyclopedia cuts across these artificial boundaries by taking an approach that emphasizes the interaction between the different aspects of research and aims to offer new solutions to understand these problems. Each of the nine sections is based around a familiar dimension of work on transportation, but brings together the views of experts from different disciplinary perspectives. Each section is edited by an expert in the relevant field who has sought chapters from a range of authors representing different disciplines, different parts of the world, and different social perspectives. In this way, the work is not just a reflection of the state of the art that serves as a starting point for researchers and practitioners, but also a pointer toward new approaches, new ways of thinking, and novel solutions to problems.

The nine sections are structured around the following themes: Transport Modes; Freight Transport and Logistics; Transport Safety and Security; Transport Economics; Traffic Management; Transport Modeling and Data Management; Transport Policy and Planning; Transport Psychology; Sustainability and Health Issues in Transportation. Some of the chapters provide a technical introduction to a topic while others provide a bridge between topics or a more future-oriented view of new research areas or challenges. While there is guidance to cross-referencing between chapters, readers are encouraged to explore the tables of contents of all the sections to get a full understanding of the issues. Much of the Encyclopedia was completed before the Covid-19 pandemic and clearly this will have changed the situation in many areas covered by this work; the advantage of this type of reference work is that relevant updates will be possible in future editions.

The Encyclopedia has only been possible because of the cooperation of a large number of people. Robert Noland, Georgina Santos, Xiaowen Fu, and Dick Ettema served as an Editorial Advisory Board identifying possible editors of sections and advising on the overall structure. The Section Editors, Edoardo Marcucci, Kevin Cullinane, Per Garder, Maria Börjesson, Edward Chung, Chandra Bhat, Maria Attard, and Carlo Prato,

carried out the work of identifying potential authors of individual chapters, commissioning these, encouraging authors and reviewing drafts. More than 600 authors and co-authors of chapters are, however, ultimately responsible for the success of this venture. Thanks are also due to the key people at Elsevier, particularly the Publishers, Andre Wolff and Oliver Walter, and the Project Managers, Sophie Harrison and Natalie Bentahar; they have shown exemplary patience over more than 3 years in bringing this work to fruition.

Rui-jun Guo
School of Transportation Engineering, Dalian Jiaotong University, Dalian, Liaoning, China

Ruimin Li
Department of Civil Engineering, Tsinghua University, Beijing, China

S.C. Wong
Department of Civil Engineering, The University of Hong Kong, Hong Kong, China

S.K. Jason Chang
Department of Civil Engineering, National Taiwan University, Taiwan

Sara Moridpour
Civil and Infrastructure Engineering Discipline, –School of Engineering, RMIT University, Melbourne, Australia

Sebastián Raveau
Department of Transport Engineering and Logistics, Pontificia Universidad, Católica de, Chile

Senthilmurugan Thyagarajan
ESC Inc, Turner-Fairbank Highway Research Center, McLean, VA, United States

Sharmili Banik
Department of Civil Engineering, IIT Madras, Chennai, Tamil Nadu, India

Shinji Tanaka
Yokohama National University, Tokiwadai, Hodogaya-ku Yokohama, Japan

Shiva Habibi
RISE, Research Institute of Sweden, Göteborg, –Sweden

Shlomo Bekhor
Faculty of Civil and Environmental Engineering, Technion-Israel Institute of Technology, Haifa, Israel

Shuhan Cao
Department of Civil and Environmental Engineering, The Hong Kong University of Science and Technology, Hong Kong, China

Shuyan Chen
School of Transportation, Southeast University, Jiangsu, China

Sigal Kaplan
Department of Geography, Hebrew University of Jerusalem, Jerusalem, Israel

Srijith Balakrishnan
Department of Civil, Architectural and Environmental Engineering, The University of Texas at Austin, Austin, TX, United States

Stacey G. Bricka
Independent Consultant, Bastrop, TX, United States

Stephen D. Boyles
Civil, Architectural and Environmental Engineering, The University of Texas at Austin, Austin, TX, United States

Taha Hossein Rashidi
UNSW Sydney, Kensington, NSW, Australia

Takahiro Tsubota
3 Bunkyo-cho, Matsuyama, Ehime, Japan

Thomas F. Rossi
Cambridge Systematics, Inc., Medford, MA, United States

Timothy D. Hau
HKU Business School, The University of Hong Kong, Hong Kong

Toru Seo
The University of Tokyo, Bunkyo-ku, Tokyo, Japan

Venkatesan Kanagaraj
Department of Civil Engineering, Indian Institute of Technology Kanpur, Kanpur, India

Wael K.M. Alhajyaseen
Qatar Transportation and Traffic Safety Center, Qatar University, Doha, Qatar

Wanjing Ma
The Key Laboratory of Road and Traffic Engineering of the Ministry of Education, Tongji University, Shanghai, P. R. China

Wenruifan Yang
University of Southern California, Department of Civil and Environmental Engineering, Los Angeles, CA, United States

William H.K. Lam
Department of Civil and Environmental Engineering, The Hong Kong Polytechnic University, Hong Kong, China

Yao-Jan Wu
Smart Transportation Lab Department of –Civil and Architectural Engineering and Mechanics, University of Arizona, Tucson, AZ –United States

Yasuhiro Shiomi
Ritsumeikan University, Kusatsu, Shiga, Japan

Yetis Sazi Murat
Pamukkale University, Faculty of Engineering, Civil Engineering Department, Denizli, Turkey

Yi Guo
University of Cincinnati, Cincinnati, OH, United States

Yingjiu Pan
School of Transportation, Southeast University, Jiangsu, China

Young-Joon Seo
School of Economics & Trade, Kyungpook National University, Daegu, Republic of Korea

Yu (Marco) Nie
Department of Civil and Environmental Engineering, Northwestern University, Evanston, IL, United States

Yumin Cao
Tongji University, Shanghai, China

Yusak Susilo
Institute for Transport Studies, University of Natural Resources and Life Sciences, Vienna, Austria

Zaili Yang
Liverpool Logistics Offshore and Marine Research Institute (LOOM), Liverpool John Moores University, Liverpool, United Kingdom

Zhanmin Zhang
Department of Civil, Architectural and Environmental Engineering, The University of Texas at Austin, Austin, TX, United States

Zhi-Chun Li
School of Management, Huazhong University of Science and Technology, Wuhan, China

CONTENTS OF ALL VOLUMES

<i>Editorial Board</i>	<i>v</i>
<i>Introduction</i>	<i>vii</i>
<i>Contributors to Volume 4</i>	<i>ix</i>

VOLUME 1

Introduction to Transportation Economics	1
Market Failures and Public Decision Making in the Transport Sector <i>Bruno De Borger and Stef Proost</i>	2
Demand for Freight Transport <i>José Holguín-Veras and Diana G. Ramírez-Ríos</i>	7
Cost Functions for Road Transport <i>José Manuel Vassallo</i>	13
Future of Urban Freight <i>Russell G. Thompson</i>	20
Operation Costs for Public Transport <i>Marco Batarce</i>	26
Natural Monopoly in Transport <i>André de Palma and Julien Monardo</i>	30
Freight Costs: Air and Sea <i>Yulai Wan and Dong Yang</i>	36
Transport Production and Cost Structure <i>Ricardo Giesen and Darío Farren</i>	46
The Concept of External Cost: Marginal versus Total Cost and Internalization <i>Sofia F. Franco</i>	56
Value of Time <i>John J. Bates</i>	67
Valuation of Carbon Emissions <i>Svante Mandell</i>	72
Valuation of Travel Time Variability Using Scheduling Models <i>Katrine Hjorth</i>	76

Value of Crowding <i>Daniel Hörcher</i>	84
What Drives Transport and Mobility Trends? The Chicken-and-Egg Problem <i>Nathalie Picard</i>	89
Pricing Principles in the Transport Sector <i>Bruno De Borger and Stef Proost</i>	95
Long-Run Versus Short-Run Valuations <i>Stefanie Peer</i>	102
Value of Noise <i>Jon P. Nelson</i>	106
The Value of Life and Health <i>Henrik Andersson</i>	114
The Value of Security, Access Time, Waiting Time, and Transfers in Public Transport <i>Raquel Espino, Juan de Dios Ortúzar, and Luis I. Rizzi</i>	122
Demand for Passenger Transportation <i>Kenneth A Small and Robin Lindsey</i>	127
Real-World Experiences of Congestion Pricing <i>Charles Raux</i>	134
Distributional Effects of Congestion Charges and Fuel Taxes <i>Jonas Eliasson</i>	139
The Bottleneck Model <i>Dereje Abegaz and Yili Tang</i>	146
Dynamic Congestion Pricing and User Heterogeneity <i>Kathrin Goldmann and Gernot Sieg</i>	150
Economics of Parking <i>Daniel Albalade and Albert Gragera</i>	159
Loss Aversion and Size and Sign Effects in Value of Time Studies <i>Andrew Daly</i>	165
Intertemporal Variation of Valuations <i>James Fox</i>	170
The Rebound Effect for Car Transport <i>Bruno De Borger, Ismir Mulalic and Jan Rouwendal</i>	174
Elasticities for Travel Demand: Recent Evidence <i>Fay Dunkerley, Charlene Rohr and Mark Wardman</i>	179
Parking Price Elasticities <i>Stephan Lehner</i>	185
The Pareto Criterion and the Kaldor Hicks Criterion <i>Harald Minken</i>	190
Social Discount Rates <i>Lars Hultkrantz</i>	195
Cross-Elasticities between Modes <i>Mark Wardman and Jeremy Toner</i>	201
First-Best Congestion Pricing <i>Moez Kilani</i>	209

Ethical Aspects-Can We Value Life, Health, and Environment in Money Terms? <i>Jose M. Grisolia and Ken Willis</i>	216
Car tolls, Transit Subsidies for Commuting, and Distortions on the Labor Market <i>Ioannis Tikoudis¹ and Kurt Van Dender¹</i>	221
Demand Management and Capacity Planning of Airports <i>Stephen Ison and Lucy Budd</i>	227
Dealing With Negative Externalities: Low Emission Zones Versus Congestion Tolls <i>Valeria Bernardo, Xavier Fageda, and Ricardo Flores-Fillol</i>	231
The Rule-of-a-Half and Interpreting the Consumer Surplus as Accessibility <i>Mogens Fosgerau and Ninette Pilegaard</i>	237
Producer Surplus <i>Chau Man Fung</i>	242
The Robustness of Cost-Benefit Analyses <i>Morten Welde and James Odeck</i>	249
The GDP Effects of Transport Investments: The Macroeconomic Approach <i>James Laird and Daniel Johnson</i>	256
The Mohring Effect <i>Hugo E. Silva</i>	263
Public Transport Fare and Subsidy Optimization <i>Qianwen Guo and Zhongfei Li</i>	267
Transportation Equity <i>Rafael H. M. Pereira, and Alex Karner</i>	271
Impact of Transport Cost-Benefit Analysis on Public Decision-Making <i>Niek Mouter</i>	278
Causal Inference for Ex Post Evaluation of Transport Interventions <i>Daniel J. Graham</i>	283
Transport Cost and Location of Firms <i>Adelheid Holl</i>	291
Commuting, the Labor Market, and Wages <i>Jan Rouwendal, and Ismir Mulalic</i>	297
How to Buy Transport Infrastructure <i>Johan Nyström</i>	302
Procurement of Public Transport: Contractual Regimes <i>Andrew Smith, and Chris Nash</i>	308
The Mono-Centric City Model and Commuting Cost <i>Zhi-Chun Li, and Ya-Juan Chen</i>	315
Value of Time in Freight Transport <i>Gerard de Jong</i>	321
The Economics and Planning of Urban Freight Transport <i>Edoardo Marcucci, Valerio Gatta, and Michela Le Pira</i>	326
Incentives in Public Transport Contracts <i>Andreas Vigen</i>	332
Transportation Improvements and Property Prices <i>Alex Anas</i>	337

Transport Infrastructure Effects on Economic Output: The Microeconomic Approach <i>Patricia C. Melo</i>	347
Wider Economic Impacts of Transport Investments <i>Anthony J. Venables</i>	355
Employment Effects of Transport Infrastructure <i>Anna Matas, and Javier Asensio</i>	360
Regulatory Reforms and Competition in Public Transport <i>Didier van de Velde</i>	365
How to Finance Transport Infrastructure? <i>Tiziana D'Alfonso, and Giuseppe Catalano</i>	371
Congestion, Allocation and Competition on the Railway Tracks <i>John Armstrong, and John Preston</i>	378
Public Private Partnership <i>David Meunier, and Emile Quinet</i>	385
Airline Economics <i>Anming Zhang, Yahua Zhang, and Zhibin Huang</i>	392
Privatization and Deregulation of the Airline Industry <i>Achim I. Czerny, and Hao Lang</i>	397
Price Discrimination and Yield Management in the Airline Industry <i>Guoquan Zhang, Colin C.H. Law, Yahua Zhang, and Hangjun Yang</i>	404
Regulation and Competition in Railways <i>Chris Nash, and Andrew Smith</i>	409
Cycling Economics <i>Bert van Wee</i>	414
The Economic Rationale for High-Speed Rail <i>Ginés de Rus</i>	419
Rail Cost Functions <i>Kristofer Odolinski, and Phill Wheat</i>	425
Transport and International Trade <i>Siri Pettersen Strandenes</i>	431
Maritime Economics: Organizational Structures <i>Kevin P.B. Cullinane</i>	436
Port Planning and Investment <i>Jasmine Siu Lee Lam</i>	443
Estimating the Capital Stock of Transport Infrastructure <i>Heike Link</i>	449
The Economics of Reducing Carbon Emissions From Air and Road Transport <i>Olga Ivanova</i>	457
Regulation and Financing of Toll Roads <i>Marco Ponti</i>	464
Are Megaprojects too Transformational for Cost-Benefit Analysis? <i>Tom Worsley</i>	470
Economics of Transportation Safety <i>Ian Savage</i>	476

Cost Overruns of Transportation Infrastructure Projects <i>James Odeck, and Morten Welde</i>	483
The Downs-Thomson Paradox <i>Joel P. Franklin</i>	490
Policy Instruments for Plug-In Electric Vehicles: An Overview and Discussion <i>Jake Whitehead, Patrick Plötz, Patrick Jochem, Frances Sprei, and Elisabeth Dütschke</i>	496
Vertical and Horizontal Separation in the European Railway Sector and Its Effects on Productivity <i>Pedro Cantos-Sánchez</i>	503
How will Autonomous Vehicles Impact Car Ownership and Travel Behavior <i>Patrick M. Bösch, Felix Becker, Henrik Becker, and Kay W. Axhausen</i>	508
Policy Instruments to Reduce Carbon Emissions from Road Transport Computable General Equilibrium Analysis in Transportation Economics <i>Johannes Bröcker</i>	520
Estimation of Value of Time <i>Stefan Flügel, and Askill H. Halse</i>	527
The Taxation of Car Use in the Future <i>Griet De Ceuster, and Inge Mayeres</i>	534
Cost-Benefit Analysis and Other Assessment Techniques: Contrasts and Synergies <i>Paolo Beria</i>	540
Demand for Air Travel and Income Elasticity <i>Jing Lu, Yucan Meng, Changmin Jiang, and Cheng Lv</i>	547
Generalized Cost for Transport <i>Jepppe Rich</i>	555
The Impact of Electric Vehicles on Energy Systems <i>Patrick E.P. Jochem, Jake Whitehead, and Elisabeth Dütschke</i>	560
Uber versus Taxis <i>Georgina Santos</i>	566
Contract Efficiency in Public Transport Services <i>Philippe Gagnepain, and Marc Ivaldi</i>	572
Company Cars <i>Stefan Gössling</i>	580
Transportation Network Companies (TNCs) and the Future of Public Transportation <i>Susan Shaheen, and Adam Cohen</i>	584
Public Transport in Low Density Areas <i>Jani-Pekka Jokinen, Leif Sörensen, and Jan Schlüter</i>	589
Market Failures in Transport: Direct and Indirect Public Intervention <i>Federico Boffa, and Alberto Iozzi</i>	596
The Braess Paradox <i>Anna Nagurney, and Ladimer S. Nagurney</i>	601
VOLUME 2	
Introduction to Transportation Safety and Security <i>Per Gårder</i>	1

The Concept of “Acceptable Risk” Applied to Road Safety Risk Level <i>Claes Tingvall</i>	2
Crash Not Accident <i>Robert A. Scopatz</i>	6
Age and Gender as Factors in Road Safety <i>Marion Sinclair</i>	11
Aggressive Driving and Road Rage <i>James E.W. Roseborough, Christine M. Wickens, and David L. Wiesenthal</i>	17
Aircraft Maintenance and Inspection <i>Alan Hobbs</i>	25
Airport Security <i>Richard W. Bloom</i>	34
Transport Safety and Security: Alcohol <i>James C. Fell</i>	40
Animal Crashes <i>Michal Bil</i>	53
Attenuators <i>Simonetta Boria</i>	63
ATV, Snowmobile, and Terrain Vehicle Safety <i>David P. Gilkey, and William Brazile</i>	77
Automobile Safety Inspection <i>Subasish Das</i>	85
Aviation Safety: Commercial Airlines <i>Clarence C. Rodrigues</i>	90
Aviation Safety, Freight, and Dangerous Goods Transport by Air <i>Glenn S. Baxter and Graham Wild</i>	98
Bicycle Collision Avoidance Systems: Can Cyclist Safety be Improved with Intelligent Transport Systems? <i>Lars Leden</i>	108
Bicycle Infrastructure <i>Rock E. Miller</i>	115
Bicycles, E-Bikes and Micromobility, A Traffic Safety Overview <i>Höskuldur Kröyer</i>	125
Bicycles: The Safety of Shared Systems Versus Traditional Ownership <i>Mercedes Castro-Nuño and José I. Castillo-Manzano</i>	139
Bridge Safety <i>Per Erik Garder</i>	144
Carsharing Safety and Insurance <i>Elliot Martin and Susan Shaheen</i>	150
Carjacking <i>Terance D. Mieth, Christopher Forepaugh, Tanya Dudinskaya</i>	157
Collision Avoidance Systems, Airplanes <i>Ivan Ostroumov and Nataliia Kuzmenko</i>	164
Collision Avoidance Systems, Automobiles <i>Erick J. Rodríguez-Seda</i>	173

Connected Automated Vehicles: Technologies, Developments, and Trends <i>Azra Habibovic and Lei Chen</i>	180
Construction Zones <i>Jalil Kianfar</i>	189
Costs of Accidents <i>Ulf Persson</i>	196
Critical Issues for Large Truck Safety <i>Matthew C. Camden, Jeffrey S. Hickman, Richard J. Hanowski, and Martin Walker</i>	200
Demerit Points and Similar Sanction Programs <i>Matúš ťucha and Kristýna Josrová</i>	210
Driver State and Mental Workload <i>Dick de Waard and Nicole van Nes</i>	216
Drugs, Illicit, and Prescription <i>Rune Elvik</i>	221
Education, Training, and Licensing <i>Matúš ťucha and Kristýna Josrová</i>	228
Elderly Driver Safety Issues <i>Mark J King</i>	233
Emergency Response Systems <i>Frances L. Edwards</i>	240
Emergency Vehicles and Traffic Safety <i>Shamsunnahar Yasmin, Sabreena Anowar, and Richard Tay</i>	247
Encouragement: Awards and Incentives <i>Fred Wegman</i>	255
Enforcement and Fines <i>Matúš ťucha and Ralf Risser</i>	263
Epidemiology of Road Traffic Crashes <i>Sherrie-Anne Kaye, Judy Fleiter, and Md Mazharul Haque</i>	269
Evacuation Planning and Transportation Resilience <i>Karl Kim</i>	276
Exposure: A Critical Factor in Risk Analysis <i>Frank Gross, PhD, PE</i>	282
Passenger Ferry Vessels and Cruise Ships: Safety and Security <i>Wayne K. Talley</i>	290
Fuel Economy Standards: Impacts on Safety <i>Kenneth T. Gillingham and Stephanie M. Weber</i>	296
Hazardous Materials Transport <i>Dr. Arjan Vincent van der Vlies</i>	304
Head-on Crashes <i>John N. Ivan</i>	311
Helicopters in Emergency Medical Response <i>Stephen J.M. Sollid, M.D., PhD</i>	316
Horizontal and Vertical Geometry <i>Victoria Gitelman</i>	322

Human Factors in Transportation <i>Alison Smiley, Christina (Missy) Rudin-Brown</i>	331
In-Depth Crash Analysis and Accident Investigation <i>Yong Peng, Helai Huang, and Xinghua Wang</i>	346
Incident Detection Systems, Airplanes <i>Ivan Ostroumov and Nataliia Kuzmenko</i>	351
Inequality and Traffic Safety <i>Miles Tight</i>	358
Lighting <i>John D. Bullough</i>	361
Macroscopic Safety Analysis <i>Mohamed Abdel-Aty and Jaeyoung Lee</i>	367
Motor Vehicle Crash Reportability <i>John J. McDonough</i>	380
Nominal Safety <i>Per Erik Garder</i>	386
Parking Lots <i>Maxim A. Dulebenets</i>	392
Passenger Van Safety <i>Saksith Chalermpong and Apiwat Ratanawaraha</i>	401
Passive Prevention Systems in Automobile Safety <i>B. Serpil Acar</i>	406
Pedestrian Safety, Children <i>Mette Møller</i>	415
Pedestrian Safety, General <i>Muhammad Z. Shah, Mehdi Moeinaddini, and Mahdi Aghaabbasi</i>	420
Pedestrian Safety, Older People <i>Carlo Lui</i>	429
Visually Impaired Pedestrian Safety <i>Robert S. Wall Emerson</i>	435
Photo/Video Traffic Enforcement <i>Charles M. Farmer</i>	439
Powered Two- and Three-Wheeler Safety <i>Fangrong Chang, Helai Huang, and Md. Mazharul Haque</i>	443
Railroad Safety <i>Xiang Liu and Zhipeng Zhang</i>	451
Railroad Safety: Grade Crossings and Trespassing <i>Rahim F. Benekohal and Jacob Mathew</i>	466
Recreational Boating Safety: Usage, Risk Factors, and the Prevention of Injury and Death <i>Amy E. Peden, Stacey Willcox-Pidgeon, and Kyra Hamilton</i>	477
Refuge Islands <i>Christer Hydén</i>	487
Risk Perception and Risk Behavior in the Context of Transportation <i>Martina Raue and Eva Lerner</i>	494

Road Diets <i>Robert B. Noland</i>	500
Road Safety Audits <i>Xiao Qin</i>	508
Roadside Safety Barriers <i>Dean C. Alberson</i>	513
Road Safety Management in Selected Countries <i>Paul Boase and Brian Jonah</i>	519
Roadway Pavement Conditions and Various Summer and Winter Maintenance Strategies <i>Kamal Hossain, PhD P. Eng</i>	529
Safety of Roundabouts <i>Khaled Shaaban</i>	539
Rumble Strips, Continuous Shoulder, and Centerline <i>AnnaAnund and AnnaVadeby</i>	549
Safety Culture <i>Tor-Olav Nvestad</i>	554
Safety Data Quality Management <i>Robert A. Scopatz</i>	560
School Bus Safety <i>Yousif A. Abulhassan</i>	564
School Campus Traffic Circulation <i>Dimitrios Nalmpantis</i>	568
Sexual Violence in Public Transportation <i>Vania Ceccato</i>	576
Shared Space <i>Allison B. Duncan</i>	584
Side Area Safety and Side Slopes <i>José María Pardillo-Mayora</i>	593
Simulators <i>Nichole L. Morris, Curtis M. Craig, Jacob D. Achtemeier, and Peter A. Easterlund</i>	602
Sleep-Related Issues and Fatigue <i>Prof Marion Sinclair and Estelle Swart</i>	611
Speed Governors and Limiters <i>Christer Hydén</i>	617
Speed Limits on Rural Highways <i>Peter Tarmo Savolainen and Timothy Jordan Gates</i>	622
Speed Limits on Urban Streets <i>Anna Bray Sharpin, Claudia Adriazola-Steil, Ben Welle, and Natalia Lleras</i>	632
Speed-Reducing Measures <i>Vinod Vasudevan</i>	641
Striping, Signs, and Other Forms of Information <i>Kasem Choocharukul and Kerkritt Sriroongvikrai</i>	648
Suicides <i>Brendan Ryan</i>	656

Surrogate Measures of Safety <i>Nicolas Saunier and Aliaksei Laureshyn</i>	662
Targeting Transit: the Terrorist Threat and the Challenges to Security <i>Brian Michael Jenkins</i>	668
The Swedish Vision Zero: A Policy Innovation <i>Matts-Åke Belin</i>	675
Tire Safety <i>Saied Taheri</i>	681
Town Gates: Section on Transport Safety and Security <i>Charles Tijus</i>	685
Traffic Flow Volume and Safety <i>Athanasios Theofilatos and Apostolos Ziakopoulos</i>	692
Traffic Safety and Security of Taxis and Ride-Hailing Vehicles <i>Zhe Wang, Helai Huang, and Ye Li</i>	699
Traffic Signals and Safety <i>Andrew P. Tarko</i>	706
Tunnels, Safety and Security Issues-Risk Assessment for Road Tunnels: State-of-the-Art Practices and Challenges <i>Konstantinos Kirytopoulos, Panagiotis Ntzeremes, and Konstantinos Kazaras</i>	713
Understanding, Managing, and Learning from Disruption <i>Karl Kim</i>	719
Use/Analysis of Crash Data and Underreporting of Crashes <i>Mohammadali Shirazi and Dominique Lord</i>	726
Utility Poles <i>Lai Zheng and Tarek Sayed</i>	731
Value of Life and Injuries <i>David A. Hensher</i>	737
Effects of Weather <i>Maria Pregnolato, Amirhassan Kermanshah, and Wisinee Wisetjindawat</i>	742
Wrong-Way Driving on Motorways <i>Huaguo Zhou and Md Atiquzzaman</i>	751

VOLUME 3

Freight Transport and Logistics <i>Sharon Cullinane and Kevin Cullinane</i>	1
Expanding the Perspective of Logistics and Supply Chain Management <i>David J. Closs</i>	8
Logistics and Supply Chain Management Performance Measures <i>David B. Grant and Sarah Shaw</i>	16
Economic Regulation/Deregulation and Nationalization/Privatization in Freight Transportation <i>Wayne K. Talley</i>	24
Freight Transport Policy <i>Luca Zamparini and Aura Reggiani</i>	29

Planning and Financing Logistics Spaces <i>Nicolas Raimbault</i>	35
Supply Chain Risk Management: Creating the Resilient Supply Chain <i>Richard Wilding</i>	41
Transportation Safety and Security <i>Maria G. Burns</i>	47
Resilience in Freight Transport Networks <i>Zhuohua Qu, Chengpeng Wan, and Zaili Yang</i>	53
Environmental Sustainability in Freight Transportation <i>Lisa M. Ellram</i>	58
Sustainable Logistics, CSR in Logistics, and Sustainable Supply Chain Management <i>Maria Björklund and Maja Piecyk-Ouellet</i>	64
Information Sharing and Business Analytics in Global Supply Chains <i>Prof Usha Ramanathan and Prof Ramakrishnan Ramanathan</i>	71
Logistics Information Systems <i>Petri Helo and Javad Rouzafzoon</i>	76
Factors Affecting the Selection of Logistics Service Providers <i>Aicha AGUEZZOUL</i>	85
Logistics Service Performance <i>Kee-hung Lai, Jinan Shao, and Yongyi Shou</i>	89
The World Bank's Logistics Performance Index <i>Christina K. Wiederer cwiederer, Jean-François Arvis, Lauri M. Ojala, and Tuomas M. M. Kiiski</i>	94
Outsourcing Logistics Functions <i>Evi Hartmann, Hendrik Birkel, and Matthias Kopyto</i>	102
Freight Transport and Logistics in JIT Systems <i>James H. Bookbinder and M. Ali Aelkū</i>	107
Supply Chain Finance <i>Erik Hofmann</i>	113
Packaging Logistics <i>Jesús García-Arca, Alicia Trinidad González-Portela Garrido, and J. Carlos Prado-Prado</i>	119
The Bullwhip Effect <i>Jan C. Fransoo and Maximiliano Udenio</i>	130
Blockchain Applications in Logistics <i>Yingli Wang</i>	136
Logistics in Asia <i>Shong-lee Ivan Su</i>	143
Logistics in the Developing World <i>Charles Kunaka</i>	150
Freight Network Modeling <i>Lóránt Tavasszy and Yousef Maknoon</i>	157
National Freight Transport Models <i>Gerard de Jong</i>	162
Freight Flows in Cities <i>Genevieve Giuliano</i>	168

Urban Logistics and Freight Transport <i>Michael Browne, José Holguín-Veras, and Julian Allen</i>	178
Omni-Channel Logistics <i>Tom Van Woensel</i>	184
Humanitarian Logistics <i>Gyöngyi Kovács and Diego Vega</i>	190
Optimization of Humanitarian Logistics <i>M. Teresa Ortuño, Jose M. Ferrer, Inmaculada Flores, and Gregorio Tirado</i>	195
Event Logistics <i>Rev. Ruth Dowson and Dan Lomax</i>	201
Reverse Logistics <i>Dale S. Rogers and Ronald S. Lembke</i>	208
E-Tailing and Reverse Logistics <i>Sharon Cullinane</i>	219
Green Routing of Freight Vehicles <i>Tolga Bektaş</i>	224
Freight Mode Choice <i>Hyun Chan Kim and Alan Nicholson</i>	231
The Value of Time in Freight Transport <i>María Feo-Valero, Amaya Vega, and Bárbara Vázquez-Paja</i>	236
Behavioral Research in Freight Transport <i>Edoardo Marcucci, Valerio Gatta, and Michela Le Pira</i>	242
Container (Liner) Shipping <i>Theo Notteboom</i>	247
Bulk Shipping Markets: An Overview of Market Structure and Dynamics <i>Manolis G. Kavussanos and Stella A. Moysiadou</i>	257
Ferries and Short Sea Shipping <i>Lourdes Trujillo and Alba Martínez-López</i>	280
Shipping and the Environment <i>Karin Andersson, Selma Brynolf, Lena Granhag, and J. Fredrik Lindgren</i>	286
Energy Efficiency of Ships <i>Harilaos N. Psaraftis</i>	294
Seaports <i>Mary R. Brooks and Geraldine Knatz</i>	299
Port Hinterlands <i>Francesco Parola, Giovanni Satta, and Francesco Vitellaro</i>	305
Seaports as Clusters of Economic Activities <i>Peter W. de Langen</i>	310
Port Efficiency and Effectiveness <i>Lourdes Trujillo, María Manuela González, Casiano Manrique-De-Lara-Peñate, and Ivone Pérez</i>	316
Container Port Automation <i>Michael G.H. Bell</i>	323
Optimizing Crane Operations in Ports Scheduling of Liner Container Shipping Services	335

<i>Yuquan Du and Qiang Meng</i>	
Dry Ports	344
<i>Gordon Wilmsmeier and Jason Monios</i>	
Arctic Shipping	349
<i>Yufeng Lin, David G. Babb, and Adolf K.Y. Ng</i>	
Airfreight and Economic Development	355
<i>Kenneth Button</i>	
Air Freight Logistics	361
<i>Keith Debbage and Neil Debbage</i>	
Air Freight Marketing	369
<i>Lucy Budd and Stephen Ison</i>	
Drones in Freight Transport	374
<i>Oliver Kunze</i>	
Duty of Care in the Selection of Motor Carriers	382
<i>Thomas M. Corsi</i>	
Carrier Selection for Less-Than-Truckload (LTL) Shipments	388
<i>Dinçer Konur, Gonca Yildirim, and Bahriye Cesaret</i>	
Decarbonizing Road Freight Transport	395
<i>Heikki Liimatainen</i>	
The Rebound Effect in Road Freight Transport	402
<i>Tooraj Jamasb and Manuel Llorca</i>	
Autonomous Goods Transport	407
<i>Heike Flømig</i>	
Rail Freight	413
<i>Dr Allan Woodburn</i>	
Rail Freight Vehicles	423
<i>Maksym Spiryagin, Qing Wu, Peter Wolfs, Colin Cole, Valentyn Spiryagin, and Tim McSweeney</i>	
Eurasia Rail Freight: Enablers and Inhibitors of Future Growth	436
<i>Hendrik Rodemann and Simon Templar</i>	
Intermodal and Synchromodal Freight Transport	456
<i>Tomas Ambra, Koen Mommens, and Cathy Macharis</i>	
Pipelines	463
<i>Matthew E. Oliver</i>	
3D Printers and Transport	471
<i>Wouter P.C. Boon and Bert van Wee</i>	
The Physical Internet and Logistics	479
<i>Eric Ballot and Shenle PAN</i>	
Bicycles for Urban Freight	488
<i>Barbara Lenz and Johannes Gruber</i>	
China's Belt and Road Initiative	495
<i>Paul Tae-Woo Lee</i>	

VOLUME 4

Introduction to Traffic Management <i>Edward C.S. Chung</i>	1
Urban Motorway Management <i>John Gaffney and Hendrik Zurlinden</i>	2
Ramp Metering Application <i>John Gaffney and Hendrik Zurlinden</i>	10
City Wide Coordinated Ramp Meters <i>John Gaffney and Hendrik Zurlinden</i>	21
Variable Speed Limits for Traffic Efficiency Improvement <i>José Ramón D. Frejo and Bart De Schutter</i>	33
Hard Shoulder Running <i>Justin Geistefeldt</i>	41
High-Occupancy Vehicle (HOV) and High-Occupancy Toll (HOT) Lanes <i>Roxana J. Javid, Jiani Xie, Lijiao Wang, Wenruifan Yang, Ramina Jahanbakhsh Javid, and Mahmoud Salari</i>	45
Reversible Lanes: Guidelines, Operation and Control, Research Directions <i>Gowri Asaithambi, Venkatesan Kanagaraj, and Madhuri Kashyap</i>	52
Electronic Toll Collection <i>Azusa Toriumi</i>	60
Road Pricing-Theory and Applications <i>Kian Keong Chin</i>	68
Road Pricing 1: The Theory of Congestion Pricing <i>Timothy D. Hau</i>	74
Road Pricing 2: Short- and Long-Run Equilibrium of Road Transportation <i>Timothy D. Hau</i>	83
Road Pricing 3: The Implications for Pricing Public Transportation <i>Timothy D. Hau</i>	90
Road Pricing 4: Case Study-The Implementation of Electronic Road Pricing in Hong Kong <i>Timothy D.</i>	103
Advanced Travelers Information Systems (ATIS) <i>Chintan Advani and Ashish Bhaskar</i>	106
Travel Time Reliability <i>Sharmili Banik, Anil Kumar, and Lelitha Vanajakshi</i>	109
Traffic Incident Management <i>Ruimin Li</i>	122
Traffic Incident Detection <i>Shuyan Chen and Yingjiu Pan</i>	128
Bottleneck <i>Kentaro Wada, Toru Seo, and Yasuhiro Shiomi</i>	134
Flow Breakdown <i>Kentaro Wada, Toru Seo, and Yasuhiro Shiomi</i>	143
Recurrent Congestion <i>Takahiro Tsubota</i>	154

Nonrecurrent Congestion <i>Takahiro Tsubota</i>	158
Freeway to Arterial Interfaces <i>Abolfazl Karimpour and Yao-Jan Wu</i>	162
Arterial Road Management <i>Jiaqi Ma, Yi Guo and Adekunle Adebisi</i>	169
Signalized Intersections <i>Chaitrali Shirke</i>	178
Protected Phase <i>Jiarong Yao, Yumin Cao, and Keshuang Tang</i>	185
Permitted Phase <i>Yumin Cao, Jiarong Yao, and Keshuang Tang</i>	196
Hook Turns: Implementation, Benefits, and Limitations <i>Sara Moridpour and Amir Falamarzi</i>	203

Introduction to Traffic Management

Edward C.S. Chung, Department of Electrical Engineering, Faculty of Engineering, The Hong Kong Polytechnic University, Hong Kong SAR

© 2021 Elsevier Ltd. All rights reserved.

Traffic management concerns the guidance and control of all types of vehicles, pedestrians and cyclists with the goal of providing a safe and efficient movements of people and goods. Road based traffic management can be broadly categorized under arterial roads management, freeway management, incident management, and parking management. Many diverse users share a limited road space in urban areas. The orderly and safe movement of traffic on arterial roads are attributed to good design of uncontrolled intersection (e.g., turbo roundabout), coordinated traffic signal control and designated lanes for public transport and cyclists. Freeways are high-capacity high-speed roads designed to carry high traffic volume between urban centers. Freeways are crucial in the functioning of cities. Often freeway capacity is degraded, for example through the development of bottlenecks, resulting in congestion and reduced mobility. Ramp metering and variable speed limit (VSL) are some of the controls used to regulate traffic entering freeways and to reduce vehicle speed approaching stationary queues. Air traffic management in broad term includes services provided to an aircraft during the flight, measures applied to reduce demand temporarily when demand exceeds capacity and airspace management. Similarly, port management concerns the strategic decision-making, monitoring and controlling of ports and terminals.

The articles in this section present a range of view across topics. Topics covered include common traffic phenomena such as capacity drop, flow breakdown, and recurrent and nonrecurrent congestion. Arterial traffic management such as signal coordination, permitted and permissive phases, hook turns, signalized roundabout, turbo roundabouts, and emergency vehicle priority. Public transport aspects such as adaptive bus control, transit priority, railway crossing, and tram lane configurations and driving rules. Articles on freeway management included city wide coordinated ramp meters, VSL, hard shoulder running, reversible lane, high occupancy vehicles lanes, and high occupancy toll lanes. Incidents contribute to a significant amount of road congestion and their impact can be mitigated by early detection and quick incident clearance. For this aspect, topics covered included incident detection technologies and incident management. Active transport such as bicycle sharing, and real time information systems such as parking information systems and advance travelers information systems are covered. Besides hardware control, road pricing as an economic mechanism to include externalities cost to reduce excess demand, and free flow electronic toll collection are covered. Non-road-based transport such as air traffic management and port management are also included.

Traffic Management

Urban Motorway Management

Keeping Urban Motorways Safe and Efficient With City Wide Coordinated Ramp Meters

Optimizing Urban Motorways Networks With Ramp Meters

Introduction

Urban motorways are one of the most critical road network assets and are usually the most expensive road assets to provide, maintain, and operate. It is important they are always managed to provide the best safety and economic outcomes for the community.

Unfortunately, these important road assets are often observed to perform poorly under congested conditions even when there is considerable deployment of intelligent transport systems (ITS) assets and systems. Substandard motorway operating conditions result in more casualty crashes, longer travel times, unreliable journeys, higher energy use, and higher vehicle emissions. When bottlenecks are allowed to form anywhere in the motorway, they quickly develop and can degrade performance over many kilometers, often affecting 10 or more kilometers upstream.

There are now thousands of ramp meters operating around the world although primarily in the USA. The following quote from the Federal Highway Administration brochure ([Federal Highway Administration, 2006](#)) demonstrates the value of ramp metering systems:

"Every evaluation of the system has shown reduced accidents, reduced delay and increased volumes when metering was installed. No other traffic management strategy has shown the consistently high level of benefits in such a wide range of deployments from all parts of the country".

Pete Briglia, Puget Sound Regional Council, Seattle, Washington and Chair of the TRB Freeway Operations Committee.

Outside of the USA other countries such as the United Kingdom have focused more on other ITS tools such as variable speed limits (VSL) to optimize traffic flows. The role of VSL application in managing traffic flows is discussed in [VicRoads \(2020a\)](#). The

authors of this chapter believe ramp metering is the most effective tool for managing traffic flows on urban motorways, it is only with appropriate mainline geometry and ramp design (both entry and exit ramp) combined with the appropriate application of traffic theory using advanced control systems that significant gains in both safety and efficiency can be achieved. Enhanced optimization will occur when City-Wide Coordinated Ramp Metering (CWCRM) is fully integrated with Dynamic VSL which is currently under development in VicRoads where the integrated DVSL and ramp metering control algorithms, which is a complex problem to research and understand, have been developed and the business case for full deployment in the field is currently underway.

Ramp Metering can Provide Mixed Findings

Unfortunately, there are many mixed findings in relation to ramp meters and there are many differences in the way ramp metering is implemented around the world, and in how performance measurement is undertaken. The authors recognize that achieving sustainable and reliable traffic flow with ramp metering is a fine art and it is possible without a thorough understanding of traffic theory relating to urban motorways (VicRoads, 2020a) to invest a lot of money and resources and achieve very little sustainable economic benefit for the community.

Sometimes ramp meters can shift the location of critical bottlenecks further downstream and in doing so create stronger bottlenecks. Some forms of ramp metering only delay the onset of flow breakdown. This in itself has an economic benefit (e.g. if it delays the onset of flow break down by 10–15 min each day this benefit can be calculated). However, in large modern urban cities with high motor car usage such as Melbourne (Population > 5 million) and in cities as defined in Section 3.2.1 of VicRoads (2019b), with a strong service-based economy with high numbers of commercial vehicles, where peak periods are of 3–5 h duration with little relief in traffic flows between peaks, this is not a viable solution.

Urban motorway networks typically have highly variable and random traffic patterns and demands which change minute to minute, hour to hour, day to day and season to season, and which also change markedly over time with the growth and development of the city. What is required is an effective ramp metering regime that can deliver sustainable traffic flows, reliably with minimal delays providing benefit over the entire day, and every day a week and which responds dynamically to the constantly variable nature of system demands.

Global Trends Increasing the Importance of Traffic Control

In the context of transport, motorways are the main arteries of any major conurbation worldwide. It is important that these arteries are as far as possible protected from influences impacting on their performance (like blood clots in this analogy). While other arteries are impacted by all sorts of influences from adjacent land uses that are difficult to control (e.g., driveways, local roads entering), motorways due to the limited access to them can relatively easily be protected.

The stress on motorways is steadily increasing. This is caused by the following global trends:

- Urbanization;
- Growing affluence and hence vehicle ownership;
- Increasing separation between home and the place of work and increasing number of trip purposes other than commuting; and
- Decreasing performance of other arteries directing more traffic toward the motorway network.

Local road authorities cannot (or only to a very limited extent) influence these global trends. Their area of influence is largely limited to the roads they plan, build, operate and maintain and not to planning and population growth, for example, immigration in Australia.

Generally, a *laissez-faire* approach to motorway management should not be taken because unconstrained access to a motorway will result in congestion characterized by different types of performance losses such as:

- “Capacity Drop”, “Throughput drop” or “Flow Loss” (a major economic loss due to less vehicles being serviced from the infrastructure across an entire motorway corridor or network)
- “Speed Drop” (a major economic loss due to lower average speed resulting in cumulative hours of delay)
- “Delay Escalation” (as delay increase is not linear as speed deteriorates, i.e., the economic loss increases exponentially as motorway speeds decay).
- “Safety Drop” (increased crash risk occurs around the density values associated with flow breakdown).
- “Increased Emissions” (from driving in congested and potentially stop–start conditions and from diversions which result in longer trips).
- “Increased Energy Use” (increased fuel consumption when driving in congested and potentially stop–start conditions and from diversions which result in longer trips).
- “Decreased Reliability” (when any bottleneck sets in and the travel times increase significantly, the flow and speed outcomes can be very variable).

Ramp metering to control access to the motorway is in the area of “damage control.” There may be some negative impacts such as waiting times at the on-ramps but this is generally far outweighed by positive impacts such as the avoidance of the above performance loss phenomena. It is an important point that, with the global trends as listed above, the net benefit will only increase everywhere,

whether it is in major conurbations in middle Europe or North America or in metropolises in China or India. In the above analogy with the human body, no doctor would ever allow a patient's main arterial getting clogged as a consequence of unhealthy diet, nor can any government afford letting their most important transport infrastructure (over time) getting dysfunctional.

Ramp Meters as the Only Practical Means to Sustain Maximum Flows

Effectively managing motorway networks requires limiting the flows to all sections of the motorway to sustainable flow values based on the temporal loading of the network or corridor (based on continuously measured sub-1 min-interval real-time data). This is achieved not through managing traffic flows, but rather traffic densities at every cross-section (typically 500 m apart) throughout the network. Ramp meters when designed and operated properly and accompanied by appropriate mainline geometric design using advanced automated real-time control systems is currently the most efficient and cost-effective way to manage traffic densities and thus the safety and efficiency of urban motorways.

When implemented on a city-wide basis as in Melbourne, it can deliver sustainable and reliable traffic flows in the order of 20% more veh/lane/h at a 20 km/h higher speed with a 30% reduction in casualty crashes. This is likely to be the case for many decades to come despite promises and predictions that autonomous vehicles will solve the problem and increase traffic flow markedly. These predictions are often model-based with minimal appreciation of road design elements (i.e., there is generally no appreciation of the geometry (physics) that keep the vehicles on the road at certain speeds, traffic engineering science, or the randomness of minute to minute traffic patterns in service-based economies). The variability of trip length, vehicle mix, and the need for mandatory lane changes required just to fill up all lanes to capacity are often overlooked in these models. For example, routinely measured on Melbourne's motorways are around 2000 lane changes per hour per km on a 4-lane motorway. This high number of lane changes is the minimum necessary to keep the motorway at optimal traffic levels (VicRoads, 2019b, 2020a). However, lane changing creates an internal friction within the carriageway (i.e., "lane shear") that needs to be measured continuously (e.g., density spikes (moving vehicle clusters)) and its effects managed dynamically, in real-time with effective ramp metering.

Why are Urban Motorways Important to Manage?

Introduction

It is the importance of urban motorways as highlighted by their contribution to daily economic activity in large urban areas that justifies investment in ramp metering. In Melbourne, urban motorways represent only 7% of the total urban arterial road pavement area; however, annually they typically facilitate 40% of travel as measured in vehicle kilometers travelled (VKT)). Reliance on the motorway network to provide arterial road travel is trending upward, with a 50% share likely in the relatively near future. Transport demand across the entire road network has increased over time placing more stress on these important assets, if uncontrolled resulting in regular flow breakdown and congestion over longer periods of the day. Commensurate with this increasing stress seems to be an increasing number of fatal and serious casualty crashes across many parts of the road network. Managed motorways have been effective in reducing and maintaining lower crash rates on urban motorways (VicRoads, 2017, 2020b).

Congestion with the consequences described above (e.g., "Throughput drop" by up to 20% and "Speed drop" by up to 50%) can impact several kilometers of the motorway upstream and can trap and delay hundreds and often thousands of motorists every hour. This can affect motorists even if they are not travelling as far as the location where the flow breakdown occurred (generally the most downstream point of the congestion). The performance of the motorway can also impact the broader surface road network.

Traffic congestion is not new. Since the introduction of uninterrupted flow facilities, in the form of freeways, flow breakdown has been present and recognized as problematic. With demand now regularly exceeding capacity for longer periods of the day, congested conditions spread temporally and geographically over time. Attempts to reduce or remove motorway congestion from urban networks have been implemented, usually targeted at increasing physical capacity (e.g., adding lanes to existing facilities and/or deploying some ITS assets and systems) to meet growing demands. However, whilst physical expansion does increase the ability to service more trips per unit time and tens of thousands more trips over the day, more lanes alone does not guarantee elimination of congestion or the assurance that available road space is utilized efficiently.

Role of Managed Motorways in an Overall Transport Network

One method used by VicRoads for understanding the effective output of a motorway system is to sum all the entry or exit flows over a day (refer to Fig. 1). Across the 75 km of the urban M1 corridor, it has been calculated that up to 900,000 vehicle journeys (trips) are serviced each day, moving more than 1 million people across Melbourne. This is the equivalent of more than 1000 fully loaded and packed train trips based on Melbourne trains (6–8 car train sets). Each trip on average travels around 15–25 km on the motorway, although the trip length varies considerably by motorway route in Melbourne and by time of day.

While this type of analysis has not traditionally been undertaken on road corridors, it is representative of person trips in a section of the transport system, similar to analysis undertaken for portions of the public transport system (e.g., boarding figures). The scale of these figures clearly demonstrates the significant task that urban motorways facilitate within the transport system. Travel surveys undertaken in 2012/13 (Department of Economic Development, Jobs, Transport and Resources, 2015) estimate that 12.3 million trips are made across Melbourne every weekday, including those using public transport and active modes (walking and cycling). The

Figure 1 Weekday daily entry flows November on the M1 motorway corridor in Melbourne.

M1 motorway corridor in Melbourne alone, representing approximately 2% of the total urban arterial road pavement facilitates 6%–7% of the daily urban trips.

The cross-sectional annual average daily traffic volume (AADT) along the M1 Motorway corridor is approximately 160,000–170,000, in several locations peaking at around 220,000 vehicles/day. The above figures (i.e., the number of trips serviced when compared to AADT) imply that the average trip length is relatively short, that is trips turn over about 3–5 times along the 75 km corridor depending of the time of day. The high turnover rate combined with trip length variability over the day is just one factor revealing some of the complexity of the motorway operation due to different trip patterns being catered for as road users travel the M1 corridor.

Role of Motorways in the Economy

Due to their contribution to the broader transport task and the Victorian and Australian economies and employment and growth, the enormous scale of the work done by urban motorways and the need for sustained motorway productivity should not be underestimated. However, the lack of control on most urban motorways generally in Australia and globally, which allows flow breakdown to occur with regularity, indicates that the importance of these high cost facilities to the economy is not fully acknowledged by their asset owners.

Historically, heavy traffic flow and congestion in urban metropolitan areas used to be contained to typically 1–2-h peak periods in the morning and afternoon. As the economies in metropolitan areas have progressively shifted from manufacturing to service provision (service-based economy) the dominant travel purpose of commuting to and from a regular place of employment at the start and end of the day has also shifted. Dominant trips now include those that are associated with a range of working hours and activities that require specific road transport modes for employment (e.g., a tradesman’s mobile “workshop”, a courier’s van, a large freight vehicle or a Uber/taxi driver).

Roads are now “places of employment” with services to properties and product deliveries being a necessary component of most businesses operating efficiently—every premise (e.g., factory, retail, business, and private residence) is a potential service point every day. In a modern service-based economy, many vehicles on weekdays *usually* do not need to have more than one person in the vehicle to be considered efficient (e.g., freight, business, delivery and other services to properties *generally* only require a driver, e.g., a nanny, a painter or a cleaner). Hence measuring and having pre-defined targets for person occupancy per vehicle is not reflective of the true utilization, economic contribution, or efficiency of road transport systems (as compared to public transport with its limited origins and destinations—e.g., following fixed tracks and defined routes with limited trip purposes, e.g., commuting). This is particularly important to understand by those who measure and use person-occupancy data, as commuting trips typically comprise less than a quarter of the road transport task and thus reporting declining person-occupancy averages results in convenient stereotyping based on misunderstanding of how roads are used by the community to enable livability and the efficient supply and distribution of goods and services.

Across the day, approximately 20%–25% of trips on the motorway system and broader road network are solely commuting related (refer to Fig. 2). These figures are similar in many large cities around the world with large service based economies such as London. While there may be some periods of the day (e.g., 6 peak hours representing 25% of all hours of the day) when commuting represents a higher proportion of all trips than during other times of the day (during morning and afternoon peaks, commuting can represent 50%–60% of trips) many of these trips are chained with other activities (refer to Levinson et al., 2017).

Figure 2 Distribution of trips by purpose in Sydney. Source: Figure 4.21 of NSW Long Term Transport Master Plan, December 2012.

The other significant development is the large contribution and steady growth in the freight transport task which can be illustrated by some numbers on freight transferred from the Port of Melbourne to the urban motorway network:

- Around 3000 ships annually docking at 34 berths;
- Over 2.64 million Twenty-foot equivalent units (TEU) handled annually (equivalent to over 7200 TEU per day); and
- 1000 new motor vehicles handled per day on average.

Although freight movements from the Port of Melbourne are significant they only represent about 5% of the freight movement in urban Melbourne. The urban freight task has also seen large growth in the “Just-for-Me” (personal consumer products as fast as possible to a noncentralized location of choice) parcel and service delivery via the growth in “small white van” phenomena where products and services are often purchased on-line and delivered at any time of the day, anywhere. This may be my home, my office or wherever I may be, for example flowers to the restaurant, a dog wash to my home and taxi/car hire services, etc.

The shift in road use and increase in overall demand has extended peak periods on all arterial roads, especially urban motorways. Periods between the traditional morning and afternoon peaks are now heavily trafficked (refer to Fig. 3) and various locations within the road network now experience peak period type demands, variable congestion and reduced performance throughout the day. This is especially true on some urban motorways in Melbourne such as the M1 corridor where more than 50,000 trips per hour are serviced all day, reaching 60,000 trips per hour in peak periods.

Figure 3 Total system flows entering the M1 corridor over 24 h-15 min periods.

As a result, for example, absolute truck numbers on the West Gate Bridge in Melbourne are in the order of 30,000 per day and small commercial “white vans” are in addition to this number. It is obvious that this activity is essential for the Victorian economy and road agencies have a focus on smoothly and seamlessly processing these trips on the urban motorway network as there is currently no alternative mode of transport available to facilitate and service these trips.

Customer Expectations and the Role of the Road Operator

Finally, most important are the expectations of the customer.

Motorway optimisation is about achieving “Good quality journeys to as many people as possible” (safe, fast, and reliable with high productivity/asset utilization). Planning and designing for these objectives needs understanding and requires determination and application of “Maximum Sustainable Flow” values (refer to [VicRoads, 2019b](#)). Utilizing such values achieves a good balance between higher speed and flows as well as a low probability of flow breakdown on the section/link/route/network levels (refer to [VicRoads, 2019b, 2020a](#)).

Many highway and road agencies have traditionally structured themselves and invested in intervention tools focused on responding to unplanned events, such as incidents and other disruptions that directly impact motorway capacity. In the past, it is acknowledged that incidents were a significant cause of congestion; however, recurrent congestion due to demand induced flow breakdown is now likely to be more prevalent on most urban motorways around the world.

Available sources suggest that more than half of the total congestion delays on urban motorways in large urban centers ([VicRoads, 2019b](#)) are due to recurrent congestion, and as it is acknowledged that growing recurrent congestion also increases the likelihood of triggering compounding nonrecurrent conditions ([Gamon, 2005](#)). This shift requires road operators to change their approach to investing in motorway assets—both civil and ITS—and develop capabilities in understanding the optimal performance of networks under all types of disruption.

This in no way reduces the requirement for road operators to have the necessary tools and resources to respond to incidents and events; however, there is an observed imbalance in the commitment of resources to maintaining optimal flows. Moving forward road agencies will require to have and adequately resource both the optimization function and the incident management function (i. e., proactive avoidance of congestion and crashes, followed by rapid recovery from incidents and breakdowns). This could also significantly reduce the number of incidents occurring across urban networks (refer to [VicRoads, 2020b](#)). Additionally, the tools required for optimization have significant synergies with those required for incident management.

Effective Motorway Control is Complex and Elusive

Traditional Approaches to Design and Control of Urban Motorways usually do not Lead to Optimal Outcomes

Traditional motorway design has been based on facilities that rarely operate at, or can sustain near capacity flows. In urban environments around the world, demands now regularly exceed the capacities of existing motorways which requires a changed approach to designing and operating various motorway elements in order to limit turbulence when flows are at or near capacity. Due to the variation of operating conditions on every segment of an urban motorway, applying the same solutions to all contexts is not appropriate.

In recent decades, in addition to providing expanded road space, road operators have also invested in technology solutions (ITS) as a means to reduce congestion and increase the efficient use of available road space. Some of these methods have achieved higher efficiency for a time; however, the ability to truly optimize the utilization of motorways and sustainably limit the onset of congestion is still broadly elusive. This is in part due to insufficient sophistication or poor implementation of the control system, for example simplistic algorithms for localized or coordinated ramp metering, or implementing dynamic VSL alone without supporting demand management. In some cases, due to the lack of understanding of detailed traffic engineering science within road agencies, the choice of tools and their application can be potentially detrimental to system performance, significantly reducing safety and efficiency from the outset. In fact, some ITS tools and operational practices can actively work against each other if used inappropriately.

Identifying the causes of congestion on motorways and quantifying its impacts requires detailed and accurate data from the motorway system. It has been observed that many road agencies have limited datasets and have lacked access to a comprehensive performance monitoring system. Often the performance monitoring system has limited visualization tools and uses data which lacks accuracy and has insufficient time and space resolution. It also often lacks ease of comprehensibility by practitioners and decision makers.

In many cases the available data has been the product of motorway detection systems originally being installed for identifying general use volumes (hourly and daily data) or identifying abnormal operations such as incidents. Whilst such systems may have served their purpose when first installed, the primary cause of congestion has shifted over time from being randomly induced by incidents to being substantially recurrent due to oversaturation at points or over extended lengths of motorway. Today in Australia casualty crashes are often likely to be caused by congestion itself (or near saturated conditions) rather than being the primary cause of congestion as was the case 20 or so years ago. Significantly improved data (additional relevant metrics, higher resolution and improved quality) is required for both recognizing the detailed causes of congestion and also to have the ability to maintain stable traffic flows.

It has been observed that whilst road operators have, with good intention, attempted to reduce or eliminate the occurrence of urban motorway congestion, the adopted practices have predominantly treated observed symptoms, not necessarily the actual cause (s) of recurrent congestion. The practices adopted by many road operators are often copied from one jurisdiction to another, whether they were successful in deployment or not (i.e., success not demonstrated through appropriate performance metrics showing sustainable long-term operational performance gains), and often without sufficient understanding of the actual impacts (or system operational principles) of adopted solutions to address the unique local conditions.

A Short History of Ramp Metering

The US Experience

The US Federal Highway Administration Ramp Management and Control Handbook ([Federal Highway Administration, 2006](#)) indicates that the first ramp metering was installed in 1963 on Chicago's Eisenhower Expressway. Ramp metering was developed as a technique to manage traffic demand following the launch of the Interstate Highway Program to address freeway flow problems associated with congestion and safety.

The initial application of entry ramp metering used a police officer stationed on the entrance ramp to stop traffic and release vehicles one at a time at a rate determined from a pilot detection program. This use of metering followed successful tests of the effectiveness of metering traffic entering New York tunnels and ramp closure studies in Detroit ([Piotrowicz and Robinson, 1995](#)).

The Minnesota Department of Transportation (Mn/DOT) has used ramp meters since 1969. In 2000 the Minnesota Legislature required Mn/DOT to study the effectiveness of ramp meters in the Twin Cities Region ([Cambridge Systematics Inc., 2001](#)) by conducting a shutdown study, that is comparison of the situations with and without ramp meters active. The evaluation report by [Cambridge Systematics Inc. \(2001\)](#) indicated significant benefits of ramp metering in the following areas:

- Traffic volumes and throughput
- Travel time
- Travel time reliability
- Safety
- Emissions
- Fuel consumption
- Benefit/cost analysis

There are now thousands of ramp meters operating in the USA. This is seen as a measure of the benefits of ramp metering installations. The following quote from the Federal Highway Administration brochure ([Federal Highway Administration, 2006](#)) demonstrates the value of ramp metering systems:

"Every evaluation of the system has shown reduced accidents, reduced delay and increased volumes when metering was installed. No other traffic management strategy has shown the consistently high level of benefits in such a wide range of deployments from all parts of the country".

Pete Briglia, Puget Sound Regional Council, Seattle, Washington and Chair of the TRB Freeway Operations Committee.

Pioneering Endeavours of Ramp Metering in Melbourne (1971–today)

The first ramp metering in Australia was provided in Melbourne on the South Eastern Freeway (now the M1 - Monash Freeway/Southern Link) at the Gibdon Street entry ramp. The ramp metering was initiated in 1971 by Mr. Kerras Burke of the Highways Division of the Melbourne and Metropolitan Board of Works (MMBW). The rate of vehicle entry to the freeway was based on data from detectors on the freeway. The traffic was regulated by varying the phase times at traffic signals at the entry ramp from the Gibdon Street/Barkly Avenue intersection. The metering had limited success due to the high freeway flows. The limited spare capacity resulted in low ramp phase time for allowing additional vehicles to enter from the ramp. The release of short platoons from the controlling signals at the top of the ramp (rather than signals close to the nose with one vehicle per green) was also less than desirable. The metering was eventually deactivated due to driver complaints about short phase times, lack of publicity to inform motorists, noncompliance and lack of enforcement.

Some 30 years later in 2002, VicRoads commenced the installation of ramp metering at motorway interchanges to reduce motorway traffic congestion and to improve merging. The entry ramp metering operated in an isolated manner with several fixed time cycles to manage the rate at which vehicles could join the motorway. Over the next few years, 11 more ramp meters were successfully installed, dependent on what the objectives of the assessment were. These ramp meters were initially seen as effective as they increased merge capacity and stability near the ramp merge and delayed the onset of flow breakdown sometimes by only a matter 10–15 min.

However, when a systemwide network performance analysis was undertaken, it was shown that improving the merge capacity alone and allowing more vehicles to enter the system could also during some peak periods increase the strength of other latent or critical bottlenecks further downstream, resulting in further degradation of the system that may not have occurred before the ramp meters were installed. Hence a new approach to ramp metering was needed which would take a helicopter view of the network and make sure that all traffic arriving at bottleneck areas could be effectively managed and also that ramp queues could be managed more effectively to limit interference with the arterial road network.

In 2008, a trial of six sequential dynamic coordinated ramp meters resulted in increased motorway performance and improved control to minimize flow breakdown. This was based on the effective management of inflows over a length of motorway to match the capacity of the mainline at each merge as well as at other critical bottlenecks. Due to the success of the trial by 2010 VicRoads installed over 60 coordinated ramp meters to manage the entire M1 Motorway within urban Melbourne. A key objective of this installation was to guarantee equity of access along the entire corridor by balancing queue lengths and waiting times. Subsequently Melbourne now has around 130 ramp meters installed on more the 50% of the network including numerous motorway-to-motorway ramp meters at system interchanges with many more presently under construction. Notably, the first system interchanges metered were associated with private toll roads interfacing with the state managed urban motorways. Today ramp metering and other managed motorway tools are supported by managed motorway policy such as it is mandatory on all new urban motorway and motorway upgrade projects in urban Melbourne.

Toward Contemporary Approaches to Design and Control of Urban Motorways Leading to Optimal Outcomes

Within the context described in above, sustained motorway optimization has remained elusive. In most urban networks, peak hour demand still exceeds capacity, that is not all trips can be facilitated at the desired time of day. The gap between *laissez-faire* performance (unmanaged operation resulting in flow breakdown and more crashes) and the desired state (stable and sustained high flow) can be closed by thorough intelligent investigation of the problem and deployment of solutions. The incorporation of state-of-the-art motorway design and traffic control maintains higher speeds at optimum flows for best productivity and also lower traffic density, the latter clearly showing a significant reduction in crash risk (refer to encyclopedia chapters on *Ramp Metering Application* and *City-Wide Coordinated Ramp Metering*).

The Journey Toward Improved Ramp Metering Application

Performance Measurement the Key to Understanding and Control

Without the important pioneering experiences with ramp metering by Dolf May and many others and those associated with early ramp metering deployments in Melbourne, VicRoads would not have progressed to where ramp metering applications have advanced to today (refer to encyclopedia text on Urban Motorway Management).

In 2002, VicRoads realized it could “no longer afford to build as many new roads as in the past and still continue to meet peak localized demands or overall peak network demands.” At the same time, VicRoads had developed advanced motorway performance monitoring and assessment tools that showed VicRoads executive leadership, the potential gains to be achieved from efficient motorway operation. This only became obvious when the loss of productivity due to congestion occurring every day of the year on its urban motorways could be shown through synoptic charts showing the differences in the traffic volumes and speeds each day before, during and after flow breakdown and the widespread nature of the resulting congestion problem across Melbourne’s suburbs. Similarly, and as stated by Kurzhanskiy and Varaiya (2014):

“Empirical analysis of popular approaches such as High Occupancy Vehicle (HOV) and High Occupancy Toll (HOT) lane management show they are ineffective except on freeways that are inefficiently managed. New ITS technologies, such as “integrated corridor management” systems, appear to be founded on quicksand in the absence of a sufficient measurement system”.

VicRoads has found this statement to be insightful, and in many ways, it reflects the internal journey and experience where ideas and concepts often move to implementation without demonstrated evidence of sustainable beneficial outcomes.

In 2003, VicRoads developed a first-generation systematic and comprehensive motorway performance measurement and analysis tool for minute-by-minute analysis of route and system performance. These tools enable surface plots to be produced at 1-min and 500 m resolution for every day of the year, as well as one-minute time series of speed, flow and occupancy and fundamental relationships to be produced for every cross-section every day, and for each site to be integrated (e.g., minute-by-minute-traces) for the analysis of the chain of events in short time periods, that is 15 min or 1-hour periods (refer to Section 1.2 - Figs. 1 and 2 as examples).

In 2004–2005, building upon VicRoads previous ramp metering endeavors and the findings from the performance reporting, new understandings emerged of the enormous system losses (opportunity cost) of allowing motorway flow to collapse. The starkness of these findings brought VicRoads back to the drawing board to rethink through the numerous operational problem(s) of motorway networks from first principles with a view to improving system-wide efficiency and safety performance. Several years were subsequently taken out to analyse and rethink the complex problems motorways presented, and which included consultation with world leading academics in the traffic engineering field, traffic physicists and control engineering specialists. The key learnings

Figure 1 Example of electronically produced surface contours for Speed, Flow, Occupancy (SVO, occupancy as a surrogate measure for density), and productivity.

Figure 2 Speed/flow graphs for the same location showing the sequential path of (1) flow breakdown and (2) flow recovery (red line shows # consecutive 1-min intervals).

during this period which eventually lead to a new generation of motorway and ramp design and advanced control for VicRoads included:

- Recognizing the chaotic nature of traffic flows such as the randomness of traffic demands, (commercial) vehicle mix and traffic patterns (e.g., origin-destination patterns which influence lane changing rates—lane shear or carriageway friction) at the sub one-minute level;
- understanding the mechanisms involved in the formation of flow breakdown and flow recovery including understanding the various shockwave types and patterns, and their interactions, which included an understanding of both forward and backward moving waves;
- acknowledgement that traffic density along an entire route and not traffic flow was critical to understanding and improving motorway operation;
- understanding that ramp demand and ramp queue formation needed to be managed both locally and at a system level to avoid interference with the arterial road network;
- recognizing the need to develop advanced road network-wide control systems that can understand and resolve all-of-the-above complexity in real-time (e.g., 20 s intervals as a basis for measuring, assessing and responding to changing conditions);
- recognizing that accurate data was needed to drive the advanced control systems where the error in the real time data measurements had to be much lower than the control increments used by the algorithms; as a background, freeway data used by many road agencies was found to be imprecise around capacity flow values (e.g., vehicles in the act of lane changing were being double

counted, artificially increasing both carriageway flow counts and loop occupancy measurements) and the error in the flow counts was as high as 7%; and

- recognition that certain mainline and ramp geometry was inductive of motorway flow instability and thus the need to design motorways differently.

The Need for Illustrations of Fine-Grained Spatiotemporal Data

It is evident from early work in the 1960s, such as hand drawn contours of density, that new understanding occurs when we look at how motorways behave longitudinally, rather than just at a single point (detector) which represents less than 1% of the motorway length (a 2 m detected area at 500 m detector spacing) or a short motorway section like a merge area. When observed from above (i.e., taking a helicopter view), a motorway displays a lot of dynamic detail and complexity, such as vehicle interactions and varying behaviors in each motorway lane.

Since the 1960s we have witnessed large increases in the deployment of electronic measuring stations (commonly induction detector loops) and rapid developments in computer power and applications. It soon became possible to produce traffic density plots (synoptic charts) and similar plots based on other metrics (i.e., speed, flow, occupancy, and productivity) with greater ease, although not necessarily greater accuracy. These can be automatically produced each day and in some cases in real time. [Fig. 1](#) shows examples of surface contour plots produced for carriageway speed, flow, occupancy (density) and productivity. These figures illustrate their development over distance (space) and time on the Monash Freeway on one randomly selected day of the year.

Surface contour plots (e.g., a speed contour plot) of temporal data (measured over a peak period and along a corridor), where plots show metrics averaged over all lanes of a carriageway or lane based, have the potential to easily illustrate complex problems to practitioners such as traffic researchers, engineers and operators. These graphs can be analysed off-line or presented live in Traffic Management Centres (TMC) to illustrate the current and emerging traffic conditions along a route. VicRoads uses fine detailed SVO data (fine detail here is a reference to 1-min data on the carriageway level and high resolution 500 m detector spacing). This is because coarse data with low resolution hides (masks) the details of what happened, or if live what is happening now. When undertaking planning or design activities, different levels of resolution are required to determine suitable design values (refer to [VicRoads, 2019a, 2019b](#)).

It has been demonstrated that the higher the spatial and temporal resolution of the available traffic data, the more insights into the causes and occurrences of traffic flow problems the analyst can potentially get (although some level of appropriate aggregation, smoothing in presentation etc. is usually required).

There may be more than one approach to identifying cause and consequence that may indicate a potential operational problem at a motorway location, or within a corridor or network. Some potential diagnosis tools that may assist in identifying bottleneck location and in further understanding causation are listed below:

- “Surface Contour Plots” (SVO and productivity which is the mathematical product of speed and volume) over several days;
- Origin-Destination relations at intersections and along a corridor (averaged over a certain period such as an hour and temporal development); and
- Time series of speed and flow (various interval length(s)) for individual bottleneck sites (occurrence of breakdown and recovery paths) as shown in [Fig. 2](#) (hysteresis plots).

Understanding Very Small Time and Space Resolution of Data

Further examination of finer resolution data revealed that even more detail is evident in the traffic data, in particular if analysed on an individual lane level. For example, the 20 s data in [Fig. 3](#) for each of the four lanes in the top four graphs (red, blue, yellow, and green) shows they all have different lane occupancy values (where lane occupancy is used as a surrogate for density in traffic control) including many large spikes. When all lanes are displayed together (bottom left) it is possible to see that the spikes are not always simultaneously occurring in all the lanes. The black graph (bottom right) shows the result of averaging to a carriageway value—where much of the detail and complexity is lost and in some cases the magnitudes of the disturbances in the individual lanes are masked out.

The “spikes” in fine granularity data have often been interpreted as being “too noisy;” however, current investigations into such elements are indicating that the vehicle interactions that cause such spikes are likely to be a significant contributor to instability in motorway traffic flows and flow breakdown events, many of which are caused by lane changing events or aggressive drivers driving too close and suddenly braking or decelerating. Investigating the detailed information behind these spikes has helped to deepen the understanding of the inherent complexity of motorway traffic flow. Therefore, the new metering control algorithms needed to be based on understanding and working with this “noise” in order to understand and manage the real-time complexities within the motorway traffic flow.

Looking Deeper at the Vehicle Event Data

When data is observed at even finer levels, that is the vehicle event level (refer to [Figs. 4 and 5](#)) it is possible to see the details that contribute to many of the disturbances in the traffic flow including vehicles moving between lanes and the speeds of each individual vehicle. It is also possible to see how drivers place themselves within lanes with a wide scatter of wheel paths.

Figure 3 Lane and carriageway occupancy data at very fine resolution, i.e. 20 s data.

Figure 4 Lane and carriageway data at finer resolutions, i.e. vehicle event level over 24 h and 2 h.

Figure 5 Lane and carriageway data at finer resolutions, i.e. vehicle event level showing vehicle lane position within lanes (including classification of vehicles and the Zig Zag effect).

In Fig. 4 the spread of vehicles in the Median Lane (top row of data points) tends to create a wide lateral gap to the adjacent lane. This may be a function of the emergency stopping lane and horizontal geometry at this location which allows drivers to perceive it is acceptable or safer to track closer to the unoccupied emergency stopping lane. Note that where a physical shoulder is quite narrow (i.e., less than 0.5 m) there will be a shy-line effect and vehicles will on average track differently.

For example, Fig. 5 shows the lateral positions of vehicles in more detail and staggering of vehicles within lanes is observed. This has been observed and described as the “zig-zag” effect which possibly occurs as a result of motorists wanting to see further ahead during dense traffic conditions or potentially as drivers prepare to lane change, thereby positioning their vehicle closer to a lane line.

When breaking down the 1 min data further (refer to Table 1), there are 122 vehicles of different lengths, traveling at different speeds, with different destinations, etc. It is new understanding at this level of data that provides further keys to understanding and managing the complexities which leads towards how ramp meters be more effectively used to optimize motorways. In this context, both the macro- and microproblems can be understood and described stochastically (e.g., with statistical distributions) and hence the real-time-variations can be measured and controlled to provide stable flows. This is discussed in the following section.

The Complex Problems Exhibited by Urban Motorways that Ramp Meters Need to Resolve

The Microdynamics at Play Differ Every Minute Everywhere

There are many factors that can influence how efficiently motorways operate. Some of the factors are static such as the number and width of lanes, grades (hills, sags, and crests), curves, ramp locations and separations, ramp geometry and the presence (or absence) of shoulders.

Other factors are dynamic such as traffic demand (varying over short time intervals, e.g. <1 min time resolution, and from day to day), changing trip patterns (origin-destination of vehicles resulting in fluctuations in trip length on the motorway), mix of vehicles (heavy vehicle proportions, presence of motorcycles), control actions (ramp metering, speed changes, lane closures), changing environment (time of day, wet and dry conditions, variable visibility, position of sun and shadows), driver impairment or distraction and incidents and events (roadworks, stationary vehicles or objects in the road environs).

Fig. 6 shows an example of some of the multiple factors that are constantly changing and interacting on the motorway, just as different rotation patterns and pitch can impact the trajectory of a baseball.

Most, if not all, of these factors, are likely to be constantly interacting on motorways and all can contribute in some part to the operational outcomes at any point in time. Due to the interplay of these factors, **it can be very difficult, or almost impossible, to separate out the impact of individual factors.** As a result, it needs to be acknowledged that the flow outcomes of a motorway are not deterministic but are stochastic (i.e., outcomes cannot be predicted precisely).

Fig. 7 indicates how this is happening every minute of every day on every section of motorway (and at every arterial road and intersection) and in different combinations on different scales, just as a baseball is rotating in flight. For example, the OD pattern (macro) is generalized by the motorist and defines the start and end of their journey. However, there are opportunities as they make a journey to modify route choice (OD Pattern micro) including where they enter or leave the motorway based on what they observe in

Table 1 Indicative breakdown of 122 vehicles per minute passing a single point on a 4-lane motorway

No.	Time	Dir/Lane	Speed (km/h)	Class Name	Axle Count	Length (m)	Headway (s)

Data source TIRTL data logger used by VicRoads for real time operations and control.

the traffic ahead, what information they see on the VMS signs, what they hear on their radio or a result of a decision they make on-route to modify the journey for another purpose, for example, fill up with petrol or go shopping, etc. Hence, in motorway control, short-term predictions are difficult and prone to error as there are no certainties.

If road operators are to have the ability to sustain stable traffic flows, motorway control systems need increased sophistication and ability to recognize and control (<1 min) the differing conditions both on individual sections (sub-links) and across whole systems. For example, VicRoads currently controls at the 20 s level with a system designed to have minimal latency between collecting field data to central control (city wide) and returning control decisions back to field (within seconds) (VicRoads, 2017).

This is demonstrated in Fig. 8 which shows 10 consecutive weekdays on a 45 km length of motorway over the morning peak period (6 h) and reveals quite different congestion patterns every day. Common patterns are visible, but to a trained eye many

Figure 6 Multiple factors constantly interacting on the motorway.

Figure 7 Multiple rotations interacting the motorway performance.

differences are apparent. Due to these differences the fundamental diagrams would vary significantly for each of the ten consecutive days. Also, it is these differences that need to be seen in the live real-time data and acted on by advanced control systems.

The Changing Shapes of the Fundamental Diagram

Measures of flow, speed and density (occupancy) from a motorway always shift from time period to time period (e.g., minute to minute) and no two 1-hour periods or days are the same. Observation indicates that the sequence of data points returned from the field are never on the same curve, or trajectory (from minute to minute), as was previously recorded (refer to Fig. 2). The resulting shapes of the fundamental relationships will also vary from section to section on a motorway and even adjacent sections 500 m apart can show markedly different generalized forms despite the fact that from a road design and visual perspective the sections look homogeneous to the road designer and road operator. *The differences from time-period to time-period have often been ignored or smoothed by averaging, yet they have major consequences for real time traffic control and optimization.*

Whilst the fundamental diagrams are influenced by road geometry, they are also influenced by the dynamic traffic loading of the motorway. Traffic engineers have undertaken traffic studies for many decades to determine traffic patterns such as Origin-Destinations (OD) studies; however, these studies are usually only useful for determining the general macro-patterns. The micro-patterns discussed above (e.g., individual manoeuvres of any of the 122 vehicles/min shown in Table 1) greatly influence the shape of the fundamental diagram.

For example, the number of lane changing manoeuvres resulting from a particular OD pattern at the 1-min time interval level may be three or more times, or even only one-third the number of lane changes that is inferred when the hourly number is divided by 60. This lane changing friction ("lane shear") which is also a microdynamic can influence the "traffic state" greatly and thus the shape of the fundamental relationships. In traffic operations care is therefore needed when using values from any fundamental relationship diagram.

The curves and their formulae often presented in text books and which are generally used in transport models are simple lines of best fit used to represent a much broader point cloud that comes from measured data, particularly when a large sample is used (i.e.,

Figure 8 Speed surface contour plots for 10 consecutive weekdays showing different traffic patterns each day (direction of travel up the page).

30 days or greater). Therefore, the presentation of a curve in the absence of the point cloud masks the variability that is experienced in the real world by the motorist (refer to red fitted curve in [Fig. 9](#)).

[Fig. 9](#) utilizes 1-h aggregate speed and flow data measured over a 1-month period, revealing a wide range of values which represent the road user experience. The red curve shows a fitted line through the range of measured values. It should be noted that the 31 days of data used to produce this figure were analysed specifically to determine capacity curves in accordance with documented analysis processes associated with traditional capacity determination and has limited application beyond this use.

Moving on from Simplistic Numerate Constructs of Performance

The HCM ([Transportation Research Board, 2016](#)) uses numerate concepts such as Level of Service (LOS) to define the various operating characteristics for uninterrupted flow. Road user experience for each level of service and associated density ranges have been in use for many years to inform planning of uninterrupted flow facilities.

Figure 9 Typical graph of speed vs flow at a single location with a 4 Lane Cross Section (actual 1-h speed and flow data measured over 1 month). Dashed line indicates Traditional “Van Aerde” capacity.

In addition, researchers and practitioners have often used rather simple constructs such as volume-to-capacity ratios to assign single flow values to some sort of operational performance level or congestion target. It has been argued by [Lay \(2011\)](#) that such concepts are useless: “HCM LOS and volume-to-capacity ratios . . . falling into this numerate but meaningless category”. VicRoads no longer considers volume-to-capacity ratios or Level of Service (LOS) values to be useful for describing uninterrupted flow performance. Amongst practitioners there may be a misconception that LOS levels operate on a continuum (i.e., linear), however, transitions are not always smooth as the traffic condition can pass through various traffic states very quickly (sometimes in a matter of seconds, refer to [Fig. 10](#)). When it comes to density ranges or volume-to-capacity ratios, the corresponding user experience varies in the motorway domain as it depends on the number of motorway lanes and the micro- and macrofactors shown in [Fig. 6](#).

Congestion as a concept has been hard to describe and sometimes has focused solely on economically determined optimum flows uncoupled from the road user experience or any road operator’s measure of congestion. Arriving at a commonly agreed and useful definition of congestion has so far proved elusive and new metrics are needed to understand and optimize motorways. An attempt of targeting an operational optimum “Productivity” (speed $\times$ flow) is described in [VicRoads \(2019b\)](#).

How to Make Sense of the Ever-Increasing Amount and Granularity of Data (or How to Not Drown in it)

It has been stated above that traffic flow is chaotic or at least highly random because of the constant changes of influencing factors shown in [Fig. 6](#). While some of these factors follow (more or less) regular daily, weekly, or annual patterns (e.g., overall traffic demand), there are random short-term fluctuations that do not allow for the precise prediction of the overall outcome in terms of traffic flow quality.

Another way to put it is that these factors and hence the overall traffic flow outcome are (to the largest extent) not deterministic but stochastic. This means that each of them can be described by a statistical distribution or other statistical parameters and the occurrence of a particular value of such a parameter (e.g., traffic demand) has a certain likelihood. Therefore, statistical methodologies are needed, for example, to describe the entirety of the 8760 different hourly traffic demands that can be measured throughout a year.

Similarly, on the capacity side of things, the journey towards statistically describing the ever changing dynamic capacity as a result of the interactions between all the factors shown in [Fig. 6](#) that are in themselves random has not only begun but is progressively finding its way into Highway Capacity Manuals around the world (refer to [TRB, 2016](#), [Henkens and Heikoop, 2015](#); [VicRoads, 2019b](#)). Rather than on simplistic fundamental diagrams highlighting a single ‘Capacity’ value (refer to [Fig. 9](#)), this is now increasingly based on curves describing the flow breakdown probability as a function of traffic flow as shown on a per lane basis

Figure 10 Variability of density with respect to traditional Levels of Service (LOS) (1-min resolution).

in **Fig. 11**. To reflect the changed thinking, VicRoads has chosen to widely replace the term “Capacity” by “Maximum Sustainable Flow Rate” (MSFR). The figure also shows the increase in productivity (speed $\times$ flow) with growing traffic flow up to a certain point before it decreases at around 90% of the traditional “Capacity.” As an additional information, **Fig. 11** illustrates the systematically decreasing Maximum Sustainable Flow Rates (MSFR) with increasing number of carriageway lanes which is particularly due to the exponential growth in lane changing activity (i.e., friction/lane shear) needed to fill all the lanes including the inner ones to “capacity.”

These examples that can be based on the traditional SVO data are important for motorway planning, design, and operations. Regarding operations, statistical methods have been applied that appropriately describe the entirety of different operational states over a long enough period and that recommend a certain state based on this comprehensive analysis.

With the finer individual vehicle data such methodologies are still to be developed. However, some practical consequences can already be seen such as the recommendation included in (VicRoads, 2019a, 2019b) that the number of carriageway lanes should potentially be limited to no more than 5 because of the very high number of measured lane changes that increases exponentially with increasing lane number.

In the context of real-time operations that this chapter is dealing with, a comprehensive ramp metering system must be able to quickly respond to critical changes (e.g., a too high density leading to high flow breakdown and crash risks) so that density at a bottleneck can be immediately reduced (refer to the chapter on *City Wide Coordinated Ramp Metering* in this Encyclopedia).

Figure 11 Breakdown probability and productivity plotted against per-lane flow rate for various cross-section types (i.e. number of carriageway lanes).

Acknowledgment

VicRoads acknowledges the partnership and contributions of TRANSMAX as the owner and developer of the VicRoads Motorway Management system (STREAMS) and Prof. Markos Papageorgiou and Prof. Ioannis Papamichail from the Technical University of Crete in the development of the HERO Live coordinated ramp metering system used to manage Melbourne's motorways.

Control Algorithms Used by VicRoads

The HERO-LIVE ramp metering control algorithms used by VicRoads on motorways in Victoria are based on the HERO/ALINEA suite of ramp metering control algorithms. The original ALINEA control philosophy which provides local control at an individual motorway entry ramp was developed by Markos Papageorgiou (refer to [Papageorgiou et al., 1991, 1997](#)).

HERO-LIVE today is an advanced suite of integrated control engineering tools which are robust in real-world (LIVE) operations where traffic conditions can be very complex. While some algorithms can perform well within offline traffic models, taking account of real-world problems is more complicated. Real-world operations need to consider and cope with the effects of rapid changes in traffic patterns (e.g., origin–destination patterns), such as those caused by incidents. There is also the need to handle real-time data errors, noisy data and data dropouts etc. which requires advanced levels of real-time statistical processing and evaluation for every 20-s time step.

HERO-LIVE incorporates a suite of ALINEA modules that were developed for coordination of ramp meters at a number of coordinated ramps along a length of motorway. In cooperation with Markos Papageorgiou and Associates, VicRoads has been involved in ongoing development of the algorithms with a significant number of enhancements to the algorithms and new modules, since the initial on-road trial in 2008. These enhancements specifically seek to solve unique problems encountered on complex urban motorways and have made significant advancements from a reactive coordinated ramp metering system towards a City Wide Coordinated Ramp Metering (CWRM) system that optimizes motorway networks within the urban road network (e.g., a network comprising motorways and arterial roads).

The HERO-LIVE suite, which is fully deployed in the field, has proven performance improvements based on utilization of the following features:

- Dynamic start up and shut down algorithms that ensure the system only operates when required;
- Consistency with contemporary traffic theory for optimizing motorway flow;
- The contemporary control logic is based on feedback from downstream conditions in real-time to dynamically adjust signal cycle times;
- Use of occupancy from the downstream motorway bottleneck locations as the optimizing measure;
- Transparent in operation with fully configurable parameters;
- Integrated operation of local ramp control within a coordinated system based on sound operating rationale;
- Incorporation of modules for adjustments to entry flow rates based on consideration of ramp queues, and arterial road queues in some cases, as well as ramp delays;
- Potential to manage flow at motorway-to-motorway interchanges by linking upstream ramps on separate motorways;
- Ability to manage bottlenecks many kilometers (3–4 km) downstream from the nearest ramp; and
- Potential for management of multiple bottlenecks to adaptively determine and target the critical bottleneck.

The adoption of an efficient control algorithm suite is of paramount importance for a successful ramp metering system. Designing and installing the necessary entry ramp layouts and field equipment is necessary and important, but these components are not sufficient in themselves for successful operations—effective control algorithms appropriately integrated are required. The management of any road system requires intentional intervention, particularly when the system is operating close to capacity. It should no longer be acceptable to road agencies to wait until the system has broken down (failed) before interventions occur. There are clearly definable metrics for which to design and operate motorway networks with a low chance of failure, and thus various components of the control system need to activate as certain target metrics are approached to limit flows moving towards bottleneck areas before the risk of failure rises beyond manageable limits.

HERO-LIVE Coordinated Ramp Metering Operation

The HERO-LIVE suite of algorithms is a comprehensive and complete concept (and corresponding implementation software) that applies coordinated ramp metering to motorway networks of arbitrary size, topology and characteristics. A central software installation at the coordinating road authority suffices for the coordinated ramp metering control of all equipped motorways, network-wide facilitated through entry/connector ramp signals that are directly controlled by the system and operated by ramp metering optimization specialists.

All specific data related to the network, the controllable entry-ramps and the real-time traffic conditions are communicated to the central software and made accessible via the STREAMS graphical user interface (GUI). Extensions of the motorway network under control or addition of new controlled ramps may be easily accommodated using the GUI. After its configuration, HERO-LIVE operates automatically without the need for operator interventions, except for specialist analysis, fine-tuning, checking for detector faults etc. Operator intervention is also possible for incident and emergency situations.

HERO-LIVE is fully traffic-responsive (with configurable update period that may be selected as short as 20 s) and adapts automatically to the prevailing traffic conditions aiming at maximizing stable motorway throughput; while, at the same time, monitoring the current situation at the on-ramps and limiting any incurred vehicle queues or waiting times. HERO-LIVE uses real-time measurements from multiple mainline locations on the motorway network and from the on-ramps and dynamically adjusts the ramp meter cycle times. Particular attention is paid to latent motorway bottlenecks, which are the typical triggers of flow breakdown and traffic congestion, and appropriate ramp metering actions are initiated, whenever necessary, to target the prevention of traffic breakdown and delivery of sustained near capacity flows based on the integrated robust feedback control methods.

The HERO-LIVE algorithms have been conceived based on the latest insights of contemporary traffic flow theory for optimizing motorway flow; moreover, they apply a variety of powerful and proven automatic control methods that guarantee stable, robust and efficient operation on the basis of feedback principles. This distinguishes HERO-LIVE from any approaches based on heuristic constructions which may lack the fundamental feedback control principles. In addition to the theoretically sound background, HERO-LIVE decisions are transparent in operation, which enables operators to be fully aware at any time about the reasons behind the employed control actions.

Motorway bottlenecks may be due to the merge of an entry ramp, but may also be a result of other geometric or traffic factors, such as merging at a lane drop, a steep upgrade, a tight-radius curve, a bridge, a tunnel, reduced lane widths or areas with high weaving or lane changing movements, for example, just upstream of a lane gain or high-flow exit ramp.

Traffic occupancy at mainline bottlenecks (detection locations in this control context) is the principal real-time measurement used to manage traffic flow on the motorway

HERO-LIVE Modules

The HERO-LIVE suite of algorithms manages the ramp traffic flow entering the motorway by monitoring and controlling the motorway flow at each ramp merge as well as other critical bottlenecks. Ramp discharge flow calculations are based on various modules providing outputs for isolated and coordinated operation as shown in [Fig. 1](#). It is noted that in order to protect intellectual

Figure 1 HERO-LIVE coordinated ramp control structure.

property (IP) the descriptions on the following pages are limited to what has already been published in the public domain for many years.

The algorithms use flow, speed, and occupancy data in various modules summarized below.

Activation/Deactivation

This module switches the motorway ramp meters on according to preset traffic flow, occupancy and speed thresholds at the mainline bottleneck locations downstream of the ramp. The ramp meters are switched off according to preset occupancy and speed thresholds. Activation and deactivation is independently controlled at each ramp within a coordinated system. The thresholds are set with the intention of turning on the signal control before the onset of flow breakdown and turning the metering signals off when traffic flow conditions indicate that flow breakdown is unlikely.

ALINEA Core Module

A form of this module calculates the necessary ramp flow at each entry ramp for local maximization of mainstream throughput according to the ALINEA feedback control algorithm, appropriately extended to enable the handling of multiple local bottlenecks simultaneously. The calculation uses the average mainstream occupancy measurement downstream of the merge (and at multiple downstream bottlenecks) relative to targeted critical occupancy values, at which the bottleneck throughput is maximized. The targeted critical occupancy at a mainline bottleneck is either set by the user or it is dynamically calculated by the critical occupancy estimation module.

Critical Occupancy Estimation Module

This module calculates the critical occupancy at motorway bottlenecks. Where and when this module is activated, the estimated value is used in the ALINEA core module as the targeted critical occupancy value. The adjustment of the critical occupancy value considers the flow/occupancy relationship that optimizes capacity and prevents flow breakdown, as well as the path of flow recovery if flow breakdown has occurred.

Queue Estimation Module

For each controlled entry ramp, this module uses the flow measurements of the ramp entrance and ramp exit detectors, as well as the average occupancy of the detectors in the middle of the ramp to calculate an estimate of the current queue length on the ramp.

Demand Estimation/Prediction Module

This module estimates the arriving ramp demand and makes a short-term prediction based on past values of flow measurements on the ramp.

Waiting Time Estimation Module

This module estimates the waiting time (ramp delay) caused due to ramp meters operation based on past values of the ramp demand and the recent signal control operation. Options for approximate or exact estimation are provided.

Queue Control Module

For each controlled ramp, this module uses the estimate of the queue length of the ramp (calculated by the queue estimation module) and the ramp demand in order to calculate a desired ramp exit flow to minimize the risk of queue overspill. This flow value needs to be determined so that traffic can still be absorbed into the mainline, so as to minimize the potential for causing flow breakdown on the mainline.

Queue Override Module

This module enables the ramp entrance/surface road interface to be managed. In the event that the ramp queue will exceed the available ramp storage, a prespecified ramp exit flow is activated to increase the metering rate. This ramp exit flow value needs to be determined so as to avoid an excessive inflow of traffic to the mainline that may trigger flow breakdown. While optimizing the motorway throughput has benefits to the road network as a whole, consideration may also need to be given to the implications of ramp queues extending onto the surface road.

Waiting Time Control Module

This module uses the waiting time estimate provided by the waiting time estimation module to calculate the desired ramp flow in order to achieve a waiting time on the ramp that is less than a pre-specified maximum waiting time value.

HERO Coordinated Ramp Operation

The HERO module coordinates local ramp metering actions in order to enable efficient mainline control despite limited ramp storage spaces, while balancing ramp queues and providing equity between ramps in a coordinated system.

HERO is activated when a ramp operating under local control experiences queues that meet pre-set thresholds, based on the available ramp storage. In this event, the ramp becomes a “master” and engages, step-by-step, upstream ramps as “slaves.” The algorithm then balances queues between the ramps. Such clusters of coordinated ramps are created wherever and whenever necessary and may be handled simultaneously at multiple motorway locations, as required.

While the system is operating in a coordinated manner under HERO, control using ALINEA and related algorithms at each individual ramp continues according to local needs.

Minimum Queue Control Module

When coordinated ramp metering is in operation, that is, HERO has been activated, this module uses the estimate of the ramp queue length and the ramp demand to calculate a desired metered flow rate so that the minimum queue calculated by HERO is implemented. This calculation aims to make best use of available storage on coordinated ramps and to balance queues between the ramps.

Final Ramp Flow Specification Module

This module calculates the final ramp exit flow to be applied to a ramp at the next control period. In the case of local ramp metering, the final ramp flow decision is based on exit flow values calculated by ALINEA as well as consideration of the various flow values to address ramp queue and waiting time on the ramp. In the case of coordinated ramp metering, the final ramp flow is based on ALINEA as well as individual ramp queues and the balancing of queues between ramps. The final flow rate may also be adjusted to be within prespecified minimum and maximum flow rates.

Implementation Module

The implementation module calculates the cycle time (sum of green, yellow, and red) that corresponds to the final ramp flow, considering the number of lanes at the stop line. The implemented cycle time is changed for each control period within prespecified increments for cycle time increases and decreases.

Ramp Meter Operational Modes

Ramp Meters—Off (Default)

When ramp meters are not operating (default situation), the ramp, including the auxiliary storage lanes, are managed with VSL signs set to default speed limits, i.e. the VSL signs will be always on and displaying the speed limit appropriate to the operating state at that time. On motorway to motorway ramp meters the display for warning VMS on the ramp (RC2-C) will be blank unless required for other relevant traffic situations, for example, during an incident and the display on the mainline warning VMS for exiting motorists (RC3-C) will be blank unless required for some other relevant traffic situation.

Times of Operation

Ramp metering operating at an isolated ramp or within a coordinated system may be activated in a number of ways.

Dynamic Activation and Deactivation

The dynamic switch-on and switch-off of ramp meters is based on the prevailing motorway traffic conditions. A dynamic system provides traffic responsive operation that activates the ramp meter signals at any time when warranted by the motorway traffic flow

conditions that could lead to the onset of flow breakdown. The activation and deactivation thresholds are set uniquely for each ramp/bottleneck during the manual fine tuning of the system.

The switch-on criteria are based on a combination of speed, occupancy and/or volume. Different criteria are used for starting up and switching off the ramp meter signals. The switching on criteria are usually set at a predetermined threshold (determined from analysis of historical conditions) to be sure that the signals start up to keep the motorway flow stable and well before the motorway flow collapses. The criteria need to be comprehensive to avoid the signals switching on at an inappropriate time, for example high occupancy and low speeds may occur at night due to a slow moving maintenance vehicle which may even sometimes stop on a detector. Usually, stronger criteria are used for switching off the signals to ensure the signals will not start up again soon after the deactivation.

Time of Day Activation

Although no longer broadly used by VicRoads for a primary control tool, time-of-day activation may be used according to critical periods, generally morning and evening weekday peak periods. Scheduled start-up and close-down times are chosen following an analysis of motorway and entry ramp flows during the peak periods and their respective shoulder periods. Typical times of operation would be 6:00–10:00 am for the AM peak period and between 3:00 pm and 7:00 pm for the PM peak period. Other times may also be scheduled to cover known occasions outside weekday peak periods where data shows that the motorway service is at risk, for example, Saturday shopping periods or special events.

Time of day parameters may also limit the times within which dynamic activation and deactivation may occur. Under this operation the metering signals may or may not switch on, depending on whether the criteria are met. This form of control for activation is advisable during the initial operation of a new coordinated system and when testing criteria for full dynamic activation.

During Incidents and Events

During periods of light traffic flow on the motorway (when the metering signals would normally be off), there may be advantages in using the signals to manage the headway of entering traffic or to manage the traffic flow. This may be necessary at times of a lane closure or traffic flow breakdown due to planned or unplanned incidents, for example, roadworks, crashes etc., to assist in traffic management and/or to facilitate flow recovery (refer to [VicRoads 2020a](#)).

Manual Operation

At any time when considered warranted, VicRoads is able to manually switch on the ramp metering signals, override the dynamic operation or switch the metering signals off.

Manual operation of other traffic management devices, for example, speed limit and lane control signs or VMS, including modification of displayed messages is also subject to VicRoads manual control, if warranted. Manual operation within the constraints of the system overrides default and dynamic operation.

Faults and Device Failures

During a communications failure (power still available), operation of the ramp metering would occur using pre-determined fixed time signal cycles which are suitable to the day of the week and time of day. In this situation VicRoads is to initiate close monitoring of the system as well as surveillance with CCTV cameras. These signal timings are reviewed periodically to ensure their appropriateness relative to changing traffic conditions over time.

With failure of advance devices at two or more locations upstream of the ramp meters, for example, warning signs (RC2-C), speed limit signs or VMS (RC3-C), the ramp metering signals will not switch on, or if already on, the ramp metering signals will switch off.

Switching on/off Signs and Signals

Start-up Sequence

The sequence for switching on typical ramp meters and associated ramp control and warning signs is shown in [Fig. 2](#). Prior to start up the signals and RC1 and RC2 signs have no display.

1. Switch Sign RC1 and Sign RC2 to “RAMP SIGNALS ON” and activate the signals to “flashing yellow” for 10 s. Activate the reduced speed limit (if applicable).
2. Switch on the alternating messages on Sign RC2, if provided, and switch traffic signals to “solid yellow” for 4 s.
3. Switch traffic signals to “solid red” for 6 s.
4. Commence the metering cycle with the initial green and continue the metering.

Separate sequences for switching on motorway to motorway ramps are included in [VicRoads \(2020b\)](#).

Close-down Sequence

The sequence for switching off the signals is shown in [Fig. 3](#) and described below.

1. Activate traffic signals to “flashing yellow” and switch Sign RC2, if provided, to “Ramp Signals ON” only (no alternating message) for 10 s.

	Device operation and time	RC1 sign	RC2 sign	Signals
1.	Prior to 'Start Up' Signals: Off Signs: Off			
2.	'Start up' Period (10 s) Signals: Flashing yellow Signs: 'Ramp Signals On'			 Flashing Yellow
3.	'Start up' Period (next 4 s) Signals: Solid Yellow Signs: 'Ramp Signals On' / 'Prepare to Stop' alternating		 Alternating Messages	 Solid Yellow
4.	'Start up' Period (next 6 s) Signals: Solid Red Signs: 'Ramp Signals On' / 'Prepare to Stop' alternating		 Alternating Messages	 Solid Red
5.	Signals commence metering Signals: Green-Yellow-Red Signs: 'Ramp Signals On' / 'Prepare to Stop' alternating		 Alternating Messages	 Green-Yellow-Red

Figure 2 Start-up control sequence—typical ramp meter.

- Switch off Sign RC1, Sign RC2, the “flashing yellow” of the signals and return the speed limit to default or another override value (if applicable).

Separate sequences for switching on motorway to motorway ramps are included in [VicRoads \(2020b\)](#).

Operating Sequence and Cycle Times (Not Used for Design)

Signal Timings

Ramp metering operation, which is considered differently to ramp metering design, has a variable cycle time generally in the range 4.0–20 s according to the determined metering rate. The sequence times based on one vehicle per green per lane are:

- Red variable—generally within the range 2.0–18 s
- Green 1.3 s
- Yellow 0.7 s.

Ramp metering design uses an average cycle time as the basis for design (e.g., an average cycle time of 7.5 s). In operations cycle times will be variable changing as often as every 20 s around an average to accommodate fluctuations in demand within the network

	Device operation and time	RC1	RC2	Signals
1.	Signals metering (Prior to 'Close Down') Signals: Green-Yellow-Red Signs: 'Ramp Signals On' / 'Prepare to Stop' alternating		 Alternating Messages	 Green-Yellow-Red
2.	'Close Down' Commences (10 s) Signals: Flashing yellow Signs: 'Ramp Signals On'			 Flashing Yellow
3.	Switch off Signals (Close down complete) Signals: Off Signs: Off			 Signals off

Figure 3 Close-down control sequence—typical ramp meter.

in real time. Designers shall not nominate a lower cycle time than specified in [VicRoads \(2019a\)](#), in an attempt to discharge higher flow rates into the motorway for the purposes of reducing storage provision. Such an approach reduces the necessary flexibility in operation and ramps are to be designed on the bases of ramp flows that can be achieved over a 1-h period (e.g., utilizing an average cycle times of 7.5 s—refer to [VicRoads 2019a](#), Section 6.2 for further details).

During ramp metering operations, when there are no vehicles waiting at the stop line, the signals are to be held on red. This prevents the signals cycling when there are no waiting vehicles and helps to avoid driver confusion in relation to timing their arrival and deciding whether to stop or not.

The operation of more than one vehicle per green per lane (e.g., two or three vehicles per green per lane) has not been permanently implemented in Australia, although it has been used internationally (refer to [VicRoads 2019a](#), Section 6.2). Generally, it is desirable to release a single vehicle per green per lane, even if shorter cycle times need to be adopted.

The entry ramp flows that result from a range of cycle times with varying lane arrangements at the stop line are shown in [Table 1](#). In practice, within a dynamic system the cycle time is based on the ability of the freeway to accommodate entering traffic. The signals apply to all lanes at the stop line.

Pre-set time of day signal cycle settings are used as a “fall back” mode when a dynamic system experiences a fault and fail safe mode is activated.

Minimum Cycle Time (Operations)

The general minimum cycle time that provides a high entry ramp flow is 5 s for a ramp leading to a motorway merge. A general minimum cycle time of 4 s could be considered when ramp traffic enters the motorway via an added lane(s)—shaded yellow in [Fig. 4](#). The minimum cycle time would generally be observed to operate under light mainline conditions, e.g. during the fringe of the peak periods or where the upstream mainline motorway flow is interrupted due to an unplanned incident. However, low cycle time values are not appropriate in design as an average value over the design hour (refer to [VicRoads 2019a](#), Section 6.2).

Cycle times lower than the minimum indicated are not generally recommended as this could approach a situation where the discharge of vehicles is almost continuous and the metering is relatively ineffective in managing headways. However, lower cycle times during operations under certain conditions may be appropriate subject to trial and assessment of driver behavior.

Table 1 Discharge capacity (stop line lanes) and ramp storage requirements

Indicative layout ^a	Ramp design flow ^a (pc/h)	Total storage required (lane-meters)	Ramp storage ^b and cycle time ^c relative to the number of lanes at the stop line							
			1 Lane	2 Lanes	3 Lanes	4 Lanes				
			Average storage per lane (m)	Average storage per lane (m)	Average storage per lane (m)	Average storage per lane (m)	Average cycle time (s)	Average cycle time (s)	Average cycle time (s)	Average cycle time (s)
Single lane merge ^d	200	113	113	18.0

Added lane entering the freeway plus a merging lane	1900	1077							269	7.6
	2000	1133							283	7.2
	2100	1190							298	6.9
	2200	1247							312	6.5
	2300	1303							326	6.3
	2400	1360							340	6.0
	2500	1417							354	5.8
	2600	1473							368	5.5
	2700	1530							383	5.3
	2800	1587							397	5.1
	2900	1643							411	5.0
	3000	1700							425	4.8

Max wait/vehicle (min.): 4.

Storage per vehicle (m): 8.5.

No. of vehicles/green/lane: 1.

^aRamp layout and design flow are subject to the mainline capacity and mainline/ramp configuration.^bAverage storage per lane assumes lanes of equal length. Not applicable with auxiliary lanes at the stop line.^cNumbers shown in bold would only be appropriate when the mainline analysis indicates ramp demands are accommodated with spare capacity for several downstream interchanges.^dA single lane merge layout may be satisfactory for higher flows, for example a ramp flow of 1400 vehicles/h entering mainline with adequate capacity.**Maximum Cycle Time (Operations)**

The general maximum cycle time that provides a low entry ramp flow is 16 s and would be implemented when freeway mainline flow is close to or above critical values of occupancy. Higher cycle times, shaded pink in [Fig. 4](#), may be implemented subject to adopted operational management strategies and driver acceptance, such as in situations of very heavy motorway congestion, during an incident or when the motorway is recovering from an incident (refer to [VicRoads, 2020a](#)).

Mainline and Entry and Exit Ramp Design**Introduction**

The era when road reservations for motorways were planned and set aside many years earlier for the purpose of building future motorways, or when motorways were progressively built and upgraded to meet traffic demand as the city expanded as populations grew, is receding in many large urban areas. In this era, it was possible to design new and upgraded motorways by targeting forecast demand for the design life, and then applying available road and traffic design standards. In the current era, projects are generally no

Cycle time (sec)	Cycle per hour (No.)	Equivalent ramp flow per hour (veh/h)

longer just a civil design exercise. They require considerably more understanding of current problems and operation in the context of the broader road network as well as anticipated future operation and performance. The current reservations may have limited opportunities for widening of motorways or establishment of reservations to meet current demands, let alone meet forecast demands. Many corridors have reached their practical limits, especially during extended peak periods, creating a need for targeted civil upgrade improvements (based on traffic analysis) and retrofitting with traffic management devices to improve safety and efficiency and provide the ability to manage actual demand.

A further aspect of the current era is that it may not be possible to meet the traffic demands for a desirable design life for major projects where widening of existing motorways or building new links is technically feasible, but where practical limitations exist due to high cost or other constraints (for example, most tunnel options). This outcome then requires special consideration of optimizing design aspects and operational strategies to ensure they can be managed to Maximum Sustainable Flow Rates (MSFR) in real time.

Performance-based Design

In this context, performance-based design becomes a specific focus where new or upgraded infrastructure needs to bring together many elements of managed motorway operations into the design, with a focus on design and operation intent (such as safety and

productivity performance outcomes), as well as an understanding of operations and maintenance elements. New approaches require collection of traffic data, data analysis and refinement of traffic modelling which, while they may sound traditional, need to be combined with the adoption of new or appropriate design thinking. This thinking links physical features to likely operation performance such as traffic turbulence, bottleneck triggers and capacity impacts. It also requires an understanding of the managed motorway toolkit, including the relative benefits of the various traffic management systems that can guide designers and project managers in priorities. Motorway design is no longer just a geometric design and alignment exercise—it considers the impacts of multiple dynamic elements impacting driver responses and interactions in the context of the design. Designers need to be fully aware that there are now many integrated managed motorway real-time backend systems and automated decision support services requiring the provision of accurate data from the field for real-time feedback control, historical analysis and performance measurement.

The road designer and/or project delivery manager must be cognizant of the downstream operational activities that will occur in the future. These matters place particular attention on the design decision making processes and the technology provided, e.g. the precise location of vehicle detectors for richer data sets requiring high accuracy and high levels of availability. The performance-based design approach considers smooth entry into the motorway, smooth transition along the motorway (designing for variable traffic patterns and traffic demands) and smooth exit from the motorway network. Special advanced control systems are needed for both entry and exit ramp management and to ensure traffic is smoothly managed out of, and into the arterial road network and that the different traffic control systems (in Melbourne, STREAMS and SCATS) are effectively interfaced to manage demands. This section will focus on design for entry ramps including motorway to motorway connections.

Design of Ramp Meters and Entry Ramps

Overview of the Design Process

Every ramp meter has several unique roles to play to control traffic locally and as part of a larger network of ramps to ensure the supply of traffic downstream arriving at bottlenecks remains within sustainable flow limits across the entire day. The main components of the ramp meter design process at each entry ramp follows an investigation along the motorway to understand motorway mainline design, capacity and performance, including at each ramp entry to the mainline and other potential bottlenecks. The main components of the ramp metering design process are shown in Fig. 5.

The VicRoads managed motorway approach (different when compared to most other jurisdictions) is that it applies holistic principles to planning, design and operations, as well as state-of-the-art best practice (traffic theory, principles and analysis) to the traffic management control and algorithms that manage the system.

Figure 5 Ramp meter design process overview.

Historic examples exist where ramp metering signals were installed and subsequently did not meet operational expectations due to inadequate analysis, poor design, and/or misunderstanding of ramp metering principles. Performance problems may involve excessive queuing and delays or other adverse effects on both the ramp and motorway mainline. A good control algorithm may not be able to compensate for an inadequate design.

The ramp storage and discharge capacity is related to the number of lanes at the stop line as well as that of merging/added lanes, the ramp arrival flow, adopted for design, the number of vehicles per green per lane and an appropriate average design cycle time, to provide the metering of traffic into the mainline (refer to [Table 1](#)).

As discussed above, every ramp meter or motorway to motorway connection must be uniquely designed for its role in managing the motorway or broader road network. Therefore attention to detail is crucial such as ramp length and number of lanes at the stop line. Shown in [Fig. 6](#) is a typical 2 lane ramp meter, however VicRoads has many three and four lane meters with details as shown in ([VicRoads, 2019a](#)). Where the stop lines are located in relation to the ramp nose and mainline merge taper is important as vehicles need to be able to accelerate up to speed before entering the motorway. Also the placement of ITS devices and especially ramp control (VMS) signs and vehicle detectors are critical for many effective algorithm and control functions.

Figure 6 Typical motorway ramp metering signals layout—two metered lanes.

Conclusion and Findings

With the hindsight of today's knowledge and experience (i.e., 2020), the relatively simplistic beginnings of ramp metering (refer to the chapter on *Urban Motorway Management* in this encyclopedia—Section 3.2) were based on empirical evidence and have provided a solid foundation that has since lead to further advances in the design of motorways themselves to be more productive by limiting unnecessary turbulence, as well as leading to major advances in the way motorway control systems are designed and operate in real-time. This has been made possible by a combination of hands-on operational experience and the detailed data analysis using statistical techniques as described in the VicRoads comprehensive overview of contemporary traffic science in (VicRoads, 2020a) and the VicRoads Motorway Capacity Guide (VicRoads, 2019b). Significant and essential advances in data quality and availability have also led to statistical analysis techniques that can indicate the development of precursor bottleneck conditions that need to be managed before instability and flow breakdown occur (refer to VicRoads, 2019b).

Traffic congestion on urban motorways worldwide, with the corresponding impacts on safety, efficiency, CO₂ emissions, etc. occurs every day of the year, over multiple hours and many kilometers and, if uncontrolled, due to traffic growth this problem will only increase. There is often insufficient knowledge of the magnitude of the social and economic damage (usually equating to tens of millions of dollars per year on a single corridor and hundreds of millions per annum in a city the size of Melbourne) and this can be due to a lack of suitable measurement infrastructure installed and efforts to appropriately analyze the measured data.

With appropriate motorway design elements, correctly located and performing ITS devices coupled with a state-of-the-art control system and operations regime (policy and practice; refer to VicRoads 2016), it is possible to manage these assets to deliver greatly improved outcomes for the community and the economy. An evaluation of the VicRoads CWCRCM on a per lane basis has shown an increase in productivity (speed multiplied by flow) by 40%–50% and a reduction in crashes by 12% (19% reduction in fatal and 10% in serious/other crashes) compared to the before upgrade situation (VicRoads, 2017).

Investment in the advanced technologies required to improve road safety and network efficiency will at the same time provide enhanced functionality for traditional Traffic Management Centre services typically delivered by road agencies, i.e., incident management, access control, lane control and speed control enabling faster and safer incident response, clearance time and flow recovery time.

Introduction

Nowadays, many social and economic problems such as waste of time and fuel, greater accident risks, and an increase in pollution are caused by traffic jams on freeways. Due to economic or viability reasons, the construction of new freeways is not always the best solution. One promising alternative is the use of dynamic control signals such as ramp metering, reversible lanes, lane change control, and route guidance. Besides these traffic control measures, in the past years, Variable Speed Limits (VSLs) have emerged as a potential traffic management measure for increasing freeway efficiency.

The first implementation of VSLs dates back to 1970 in Germany (Zackor, 1972). During the subsequent decades, VSLs have been also applied in The Netherlands, United States, and other countries. Earlier studies assumed that, if a VSL is applied, the capacity of a freeway segment is increased due to speed harmonization within each lane and across different lanes. Thus, the main objective, beyond improving traffic safety, was to increase freeway efficiency by applying VSLs to congested bottlenecks. However, later works did not identify any capacity increase due to VSLs; even a capacity reduction is observed concluding that a substantial improvement of the traffic efficiency cannot be reached by applying VSLs to increase capacity at congested bottlenecks.

Indeed, the most recent empirical validations (Frejo et al., 2019) have shown that a reduction of the value of a VSL has the following effects on the fundamental diagram of traffic flow: an increase in the critical density, a decrease in the capacity, and a decrease in the free-flow speed. The most well-known macroscopic models that incorporate these effects of the VSLs on traffic flow are introduced in the section, Macroscopic modeling of variable speed limits on freeways for traffic efficiency improvement.

Nowadays, and based on the fact that it is not possible to directly increase the capacity of a segment by using VSLs, three main kinds of VSL control algorithms are considered in the recent literature:

- **Safety-oriented VSLs:** This kind of VSL control algorithms are applied in order to increase traffic safety by reducing the speed limit when a vehicle is approaching a congested segment or an incident or by homogenizing speeds to reduce fluctuations in traffic behavior. The safety benefits of these control algorithms have been reported in field studies. However, these applications have not yet achieved a significant improvement of the flow or the capacity.
- **VSLs for traffic efficiency improvement:** The goal of these VSL control algorithms is to avoid, resolve, or reduce traffic jams on freeways by limiting the arriving flow and, thereby, avoiding or mitigating the capacity drop. These techniques have been mainly tested by simulation and, therefore, their potential improvement in the traffic conditions relies on the model used. Moreover, the use of model-based optimal control algorithms (like Model Predictive Control) can considerably improve the Total Time Spent (TTS), emissions, fuel consumption, and other traffic performance indices, but their success highly depends on model accuracy.
- **Pollution-oriented algorithms:** Pollution-oriented VSL control algorithms, usually based on the structure of a controller designed for traffic efficiency improvement, provide a balanced trade-off between travel times, fuel consumption, and emissions. However, the reduction of the emissions that can be achieved without decreasing traffic efficiency is usually relatively low.

This work focuses on the second kind of algorithms since they have attracted most of the research attention during the last years and because they have a much higher potential (in terms of improvement of the traffic conditions). More concretely, the most

Figure 1 Desired speeds. The values used for the FD parameters are $v_{f,i} = 120$ km/h, $\rho_{c,i} = 30$ veh/(km lane), $a_i = 2.5$, $V_{c,i}(k) = 60$ km/h, $a_i = 1.4$, $A_i = 0.8$, $E_i = 3$ (for Carlson's model), $A_i = 0.889$ and $E_i = 1.78$ (for Frejo's model).

commonly used control approaches for the control of VSLs to improve traffic efficiency are presented in the section, VSL Control Algorithms for Traffic Efficiency Improvement by Mainline Metering. Furthermore, the main conclusions and major open challenges are drawn in section, Conclusions.

Macroscopic Modeling of Variable Speed Limits on Freeways for Traffic Efficiency Improvement

In model-based freeway traffic control using VSLs, an accurate, but significantly faster than real-time, prediction model is necessary for the computation of the control inputs. On the other hand, although easy-to-implement controllers do not usually need a traffic model for the computation of the control inputs, an accurate model is also necessary for calibration and validation purposes.

Two main approaches are mostly used for the traffic flow modeling:

- **Microscopic models**, which describe the longitudinal and lateral movement of individual vehicles.
- **Macroscopic models**, which mostly model traffic as a particular fluid with aggregate variables such as density, mean speed, and flow.

One of the main advantages of microscopic models is their ability to study individual vehicle motion visually, perceiving the real process using simulation software. However, microscopic models are difficult to use for model-based control due to the computational effort needed; thus, these models are usually only used for simulation and off-line tuning of controllers. On the other hand, macroscopic models are more suitable for model-based applications because they are relatively fast and have an analytical form. This work, therefore, focuses on the modeling of VSLs within the framework of macroscopic traffic models.

Within macroscopic traffic flow models, first-order models like the cell transmission model include a static speed-density relationship. On the other hand, second-order models like METANET address the speed as another state variable with an according state equation, which is capable of capturing additional dynamics and, more important, is able to model capacity drop. Therefore, this work focuses on the modeling of VSLs by modifying the second-order model METANET. It should be noted that in the literature a first-order model that includes the effects of VSL (Han et al., 2017) it can be also found. In the related literature, three main ways of including the effects of VSLs in METANET have been considered. These three approaches are presented in the further sections.

VSL Model of Hegyi et al.

The first macroscopic model for VSLs was proposed by Hegyi et al. (2004). In this model, VSLs are included by modifying the desired speed equation. When a VSL is applied, the desired speed $V_i(k)$ is computed by taking the minimum of two quantities: the speed based on the prevailing traffic conditions, and the speed caused by the VSL (affected by a compliance term):

$$V_i(k) = \min \left(v_{f,i} e^{-\frac{1}{a_i} \left(\frac{\rho_i(k)}{\rho_{c,i}} \right)}, (1 + \alpha_i) V_{c,i}(k) \right)$$

where $V_{c,i}(k)$ is the value of the speed limit on link i , α_i is a model parameter that reflects the driver compliance, $\rho_i(k)$ is the density on link i , $v_{f,i}$ is the free-flow speed, $\rho_{c,i}$ is the critical density, and a_i is a parameter of the METANET model. An example of the desired speed of a link obtained under the influence of a VSL can be seen in Fig. 1. The corresponding Fundamental Diagram (FD), the steady-state relation between flow and density, can be seen in Fig. 2.

Figure 2 Fundamental diagrams with the same parameters as Fig. 1.

Figure 3 Capacity reductions (%) with respect to the original FD with the same parameters as Fig. 1.

Assuming that the parameters of the original METANET model are known, the effect of the application of VSLs on the three characteristic parameters of the FD (critical density, free flow speed, and capacity) according to Hegyi's model is the following:

- **VSL-induced free-flow speed:** Compliance can be adjusted by parameter a and, therefore, for a given value of $\nu_{f,i}$ and $\nu_{c,i}(k)$, any value (between $\nu_{c,i}(k)$ and $\nu_{f,i}$) for the VSL-induced free flow speed can be set according to the measurements.
- **VSL-induced critical density:** The new critical density is computed by intersecting the original FD with the speed line given by the VSL-induced free flow speed or by taking the original critical density if the intersection is on the uncongested part of the FD. For a given compliance and original FD, the VSL-induced critical density cannot be adjusted (i.e., calibrated according to measured data).
- **VSL-induced capacity:** The obtained capacity reduction (with respect to the capacity corresponding to a speed limit of 120 km/h) as a function of the value of the speed limit is shown in Fig. 3. As can be seen in the figure, the capacity reduction is usually relatively small or even zero for high and intermediate speed limits. For example, for the FD shown in Fig. 2, the capacity is reduced only by about 3.65% with the VSL being half (60 km/h) of the nominal speed limit (120 km/h).

VSL Model of Carlson et al.

The second model that is commonly used in the literature was proposed by Papamichail et al. (2008) in 2008 and it has been mainly used by Carlson et al. (2010). In this model, FD parameters are modified to incorporate the influence of the VSLs. The speed ratio $b_i(k)$ (defined between 0 and 1) is used instead of the implemented value of the speed limit $V_{c,i}(k)$:

$$V_i(k) = \nu_{f,i}^*(k) e^{-\frac{1}{a_i^*(k)} \left(\rho_i \frac{(k)}{\rho_{c,i}^*(k)} \right)^{a_i^*(k)}} \quad b_i(k) = V_{c,i} \frac{(k)}{V_{\max_{c,i}}(k)} \quad \nu_{f,i}^*(k) = \nu_{f,i} b_i(k)$$

Figure 4 FD and desired speed for different levels of compliance using Frejo's model.

$$\rho_{c,i}^*(k) = \rho_{c,i}(1 + A_i(1 - b_i(k)))a_i^*(k) = a_i(E_i - (E_i - 1)b_i(k))$$

where A_i and E_i are parameters of Carlson's model.

An example of the desired speed and FD obtained with this model can be seen in **Figs. 1 and 2**.

According to Carlson's model, the three characteristic parameters of the FD change as follows:

- **VSL-induced free-flow speed:** Since compliance is not included, it is assumed that the VSL-induced free-flow speed is equal to the value of the corresponding speed limit (i.e., for steady states with low densities, the mean speed of a link will be equal the current VSL value in the corresponding link).

VSL-induced critical density: The critical density induced by a VSL can easily be adjusted in order to approach measured data by changing the parameter A_i .

VSL-induced capacity: The capacity induced by a VSL can be calibrated by adjusting the parameters E_i and A_i .

The obtained capacity reduction is shown in **Fig. 3**. As can be seen in the figure, for the given values of the model parameters, the capacity is slightly increased for high values of the VSL. On the other hand, for intermediate and low values of the VSL, there is a significant capacity reduction.

VSL Model of Frejo et al.

As previously explained, Hegyis model can be adapted for different VSL-induced free-flow speeds, but it lacks the capability of modeling different capacity reductions and critical densities due to the effects of VSLs. On the other hand, Carlson's model is able to model different VSL-induced capacities and critical densities, but it does not consider different levels of compliance.

The model proposed by Frejo et al. (2019) combines the advantages of both approaches: The effect of a VSL is modeled by modifying the FD parameters including a calibration parameter for each equation (a_i for $v_{f,i}$, A_i for $\rho_{c,i}$ and E_i for a_i):

$$V_i(k) = v_{f,i}^*(k)e^{-\frac{1}{a_i^*(k)}\left(\rho_{c,i}^*(k)\right)} \quad b_i^*(k) = \min\left(V_{c,i} \frac{v_{f,i}^*(k)}{V^{\max}}(1 + \alpha_i), 1\right)$$

$$v_{f,i}^*(k) = \min(V^{\max} b_i^*(k), v_{f,i})$$

$$\rho_{c,i}^*(k) = \rho_{c,i}(1 + A_i(1 - b_i^*(k))) \quad a_i^*(k) = a_i(E_i - (E_i - 1)b_i^*(k))$$

where $V^{\max}$ is the maximum allowed value for the VSLs.

An example of the desired speed and FD obtained with the proposed model can be seen in **Figs. 1 and 2**. According to the model, the three characteristics parameters of the FD change as follows:

- **VSL-induced free-flow speed:** Compliance with variable speed limits can be adjusted by the parameter a_i ; hence the VSL-induced free-flow speed can be freely set according to measured data. It is noted that compliance is also affecting the VSL-induced critical density and capacity. This allows to adapt an already calibrated model if the compliance changes (e.g., if the speed limit compliance is enforced by fines or other measures). In **Fig. 4**, the FDs and the desired speeds obtained for different values of the compliance are shown. The figure is equivalent to the one that would be obtained for different values of the VSL having the same compliance. It can be seen that, as expected from real traffic, the influence of the speed limits (and their compliance) is very low when the system is considerably congested.

- **VSL-induced critical density:** The critical density induced by a VSL can be adjusted in order to approximate measured data by changing the parameter A_i .
- **VSL-induced capacity:** The VSL-induced capacity can be also adjusted in order to fit measurements by using the parameters E_i and A_i .

Model Comparison

Hegyi's model can be adapted for different VSL-induced free-flow speeds, but it lacks the capability of modeling different VSL-induced capacity reductions and critical densities while Carlson's model is able to model different VSL-induced capacities and critical densities, but it does not consider different levels of compliance. On the other hand, Frejo's model can be adapted for different VSL-induced free-flow speeds, capacities, and critical densities. The main disadvantage of Frejo's model is that three parameters have to be adjusted for each link (while only one is necessary for Hegyi's model and two for Carlson's model). The additional parameter is not going to affect substantially simulation times or optimization computational load. However, the calibration effort will be accordingly increased.

As in any other modeling problem, model choice will depend on the circumstances of each case. For example, if the VSLs are only going to be applied for very low densities in a freeway with full compliance, the three models are going to perform similarly. In this case, Hegyi's model would be the best choice (since it is the simplest of the three considered models). However, if the compliance is not high and the capacity is considerably reduced when VSLs are applied or if the desired speeds are considerably changing for different values of uncongested densities the use of Frejo's model is justified (especially from a control point of view).

VSL Control Algorithms for Traffic Efficiency Improvement by Mainline Metering

Many different control algorithms have been proposed for VSLs during the last decades. This work classifies them according to their main characteristics.

Optimization-Based Versus Easy-to-Implement VSL Controllers

Two main approaches have been used in the literature for the control of VSLs in the context of traffic efficiency improvement: Optimization-based approaches and easy-to-implement controllers.

- **Optimization-based controllers:** This kind of control algorithms computes the values of the speed limits based on the minimization of a cost function. The most commonly used cost is the Total Time Spent (TTS), but also other traffic performance indices have been considered in the literature, such as emissions or fuel consumption. Optimization-based approaches using Model Predictive Control (MPC), which minimizes the cost function using a receding horizon approach, has shown to substantially improve the performance of the controlled traffic network in various simulation studies (Carlson et al., 2010). The main drawback of MPC is that the computation time quickly increases with the size of the network, making it difficult to apply centralized MPC for large traffic networks. The use of a distributed architecture (Frejo and Camacho, 2011) and/or of a suitable optimization algorithm such as the RPROP algorithm (Pasquale et al., 2016) may relieve these limitations but, unfortunately, the obtained controllers are still too complex to be implemented in real time for large networks. Moreover, MPC controllers for VSLs are not robust in case of communication or measurement errors. For this and other reasons, completely centralized control of large traffic networks is still viewed by most practitioners as impractical and unrealistic.
- **Easy-to-implement controllers:** In order to overcome the practical limitations of the optimization-based controllers, a few easy-to-implement control algorithms have been designed for the control of VSLs. The most well-known ones are SPECIALIST (Hegyi et al., 2008), MTFC (Carlson et al., 2011), and LB-VSL (Frejo and De Schutter, 2018).

Compared with optimization-based techniques, these VSLs controllers have the following advantages:

- Controller implementation is quite easy because the online computation is almost instantaneous in most cases.
 - Moreover, easy-to-implement controllers are robust against communication and measurement failures in other segments different from the bottleneck segment.
 - Finally, easy-to-implement controllers are usually more intuitive than MPC controllers for the traffic community, which is not always familiar with automatic control, as the easy-to-implement only provides the thresholds at which the VSLs have to be changed.
- **Intermediate approaches:** Other approaches, such as QL-VSL (Li et al., 2017) and SPERT (Frejo and De Schutter, 2019), propose an intermediate solution allowing an easy implementation while approaching the performance of an optimal controller (computed offline). However, unfortunately, the off-line effort needed for the training of the network (in the case of QL-VSL), or for the computation of the optimal solution (in the case of SPERT) makes that, for large-scale networks, these algorithms are still difficult to implement in practice.

Local Versus Global VSL Controllers

Some studies have shown that centralized controllers for VSLs allow, in some cases, to obtain a much greater improvement on the traffic conditions than fully decentralized (i.e., local) controllers (Frejo and Camacho, 2012). However, as previously explained, a centralized and optimization-based traffic control algorithm is quite difficult to implement in a real (i.e., medium or large) traffic networks due to the exponential growth of the computation times.

As a consequence, the use of an algorithm that properly uses communication and cooperation between different controllers to approach the centralized behavior without critically increasing computational effort can substantially improve the performance of the controlled traffic system. Accordingly, a few distributed control algorithms have been proposing for VSLs using optimization-based techniques (Frejo and Camacho, 2011).

Discrete Versus Continuous VSL Controllers

Although in the real implementations of VSL panels the displayed signals are just allowed to take a limited set of discrete values, in many previous references the VSL signals are assumed to have continuous values. However, some recent works have shown that, in some cases, converting the continuous unconstrained VSL signal into an implementable VSL signal (i.e., a discrete value respecting the safety constraints) can substantially reduce performance with respect to the ideal case.

In order to deal with this problem, in Frejo et al. (2014), the discretization of the VSL signals is obtained by solving a discrete optimization problem with a search space limited to a certain distance from the continuous MPC solution. However, this discretization entails a new optimization increasing the computational load of the controller.

On the other hand, other controllers (like SPERT or LB-VSL) directly compute a discrete implementable value for the speed limits, avoiding the need of a subsequent discretization.

Summary of VSL Control Algorithms

The following table summarizes some characteristics of some of the most well-known VSL control algorithms for increasing freeway efficiency. The second and third column refers to the computational load required during each control step and the fourth one shows which algorithms provide a directly implementable discrete solution.

The fifth and sixth columns analyze how optimal and intuitive (for the traffic community) the solution provided by each controller is. The seventh column shows the kind of congestion that can be solved by each controller. Finally, the last column comments the robustness of each controller against uncertainties and/or communication or measurement errors.

Controller	Computational Load		Solution provided	Optimality	Intuitiveness	Kinds of congestion	Robustness
	Off-line	On-Line					
Optimal (computed offline)	High	Very high	Continuous	Optimal solution (for the given demands)	Low	All	Lack of robustness
MPC	High	High	Continuous	Optimal solution (within a receding horizon)	Low	All	Lack of robustness against communication failures
Distributed MPC	High	Medium	Continuous	Optimal solution (within a receding horizon)	Low	All	Lack of robustness (only at agent level)
Hybrid MPC	High	Medium	Discrete	Optimal solution (within a receding horizon)	Low	All	Lack of robustness against communication failures
SPERT	High	Very low	Discrete	Suboptimal (based on the optimal solution)	Medium	Recurrent congestion	Robust (around typical demand)
SPECIALIST	Low	Very low	Continuous	Not based on optimal solution	Medium	Shock waves	Robust (for shock waves)
Local MTFC	Low	Very low	Continuous	Not based on optimal solution	Medium-low	Active bottlenecks	Robust (for jams caused by bottlenecks)
QL-based	Very	high	Low	Discrete	Based on reinforcement learning	Low	Recurrent bottlenecks
Robust (if properly trained)							
LB-VSL	Low	Very low	Discrete	Not based on optimal solution	High	Active bottlenecks	Robust

Integration With Other Freeway Traffic Control Measures

The combined use of VSLs and other traffic control measures has been studied in many simulation studies:

- **Optimization-based algorithms for the integrated control of VSLs and ramp metering installations:** The most widely implemented and studied freeway traffic control measure is ramp metering, which limits the traffic flow of traffic entering freeways according to current traffic conditions. There are many research works that propose integrated controllers for ramp metering installations and VSLs. In most cases, these controllers use MPC techniques, entailing a higher computational complexity than the isolated control of the VSLs but a significantly better control performance. A few relevant examples can be found in Hegyi et al. (2004), Carlson et al. (2010), and Frejo and Camacho (2012).
- **Easy-to-implement algorithms for the integrated control of VSLs and ramp metering installations:** On the other hand, only three easy-to-implement controllers have been proposed for the integrated control of VSLs and ramp metering installations: MTFC + PI-ALINEA (Carlson et al., 2014), SPECIALIST-RM (Schelling et al., 2011), and LB-TFC. In all cases, these controllers are extensions of previously proposed easy-to-implement controller for VSLs.
- **Integration with other traffic control measures:** VSLs have also been integrated with lane change control, which generates lane change recommendations or restrictions upstream of an incident or bottleneck, in Zhang and Ioannou (2017). VSLs may be also integrated with other traffic control measures, such as reversible lanes, route guidance or high-occupancy lanes. Moreover, in future works, VSLs algorithm should be adapted for a context with a high penetration of autonomous vehicles.

Conclusions

VSLs have shown to be a powerful measure for traffic efficiency improvement in many simulation studies and a few field tests.

The most common way to model VSLs in the context of freeway traffic control is by modifying a macroscopic traffic flow model, like METANET. This modification reproduces the effects of a reduction on the value of a VSL by increasing the critical density and by decreasing the capacity and the free flow speed of the corresponding segment.

Many control techniques have been proposed for VSLs for traffic efficiency improvement, which can be mainly divided into optimization-based techniques (which can achieve the best performance but are difficult to implement in real freeways) and easy-to-implement techniques (which provide a suboptimal performance but are easy to implement in real applications).

Nowadays, the most important open challenge in the field of VSLs is the real application and testing of the control algorithms that have been proposed in the literature. In fact, so far only two control algorithms for traffic efficiency improvement (SPECIALIST and MTFC) have been tested in real experiments. As a consequence, there is still a significant lack of data that hinder the analysis of the potential effects of the implementation in practice of VSLs.

Definition

Hard shoulder running is an active traffic management (ATM) strategy that incorporates the use of the hard shoulder on freeways (motorways) as a travel lane during peak hours. It is primarily used on freeway segments or corridors affected by recurring congestion due to a lack of carriageway capacity during peak hours. Hard shoulder running is implemented either as an interim solution if widening of the carriageway cannot be realized within short periods of time or as a permanent solution if alternatives to improve traffic operation are infeasible. In contrast to permanently converting the hard shoulder into a travel lane, hard shoulder running provides the additional capacity only when needed to avoid congestion, while the hard shoulder can still be used as emergency lane or for road maintenance during off-peak traffic conditions.

Hard shoulder running is also referred to as “part-time shoulder use”, “temporary hard shoulder use”, “dynamic hard shoulder use”, and a number of similar expressions. Hard shoulder running schemes can be distinguished between

- dynamic (traffic-responsive) or static (fixed-time) control of opening and closing the hard shoulder for travel,
- use of the outer or inner shoulder,
- shoulder use between adjacent interchanges, where the shoulder acts as an auxiliary lane between an entrance ramp and the next exit ramp, or continuous shoulder use on a corridor over several interchanges, and
- opening the shoulder for all types of vehicles or for specific vehicle types like buses (bus-on-shoulder) or passenger cars only.

Today, the temporary use of the outer shoulder (i.e., the right shoulder when driving on the right) for all types of vehicles with traffic-responsive control is the most common type of hard shoulder running applications worldwide. Hard shoulder running typically involves the use of traffic monitoring and control systems with gantries that include speed and lane control signs as well as video surveillance of the hard shoulder. To ensure that traffic safety is not affected by the loss of the hard shoulder as emergency lane, the speed limit that is applied during the times when the hard shoulder is in operation is usually lower than during closed hard shoulder. Implementing hard shoulder running often requires a reallocation of the carriageway cross section in order to provide a sufficient width of the shoulder that is required to be safely used by running traffic, particularly trucks. Emergency refuge areas are also added to the carriageway.

Applications

While static part-time shoulder use has been applied in the United States since the 1970s, the first dynamic (traffic-responsive) hard shoulder running schemes were implemented in Germany and the Netherlands in the late 1990s, followed by a number of segments also in other European countries in the subsequent years. Based on the gained experience, deployment guidelines for hard shoulder running in Europe were published by [EasyWay \(2012\)](#).

In Germany, the first control systems for dynamic hard shoulder running were installed on freeway (Autobahn) A4 between Refrath and Cologne-Meerheim in 1996. Subsequently, major implementations of hard shoulder running on longer freeway corridors include the A3 between Offenbach and Hanau, the A5 between Frankfurt North-West interchange and Friedberg ([Figure 1](#)), and the A99 between Munich North interchange and Haar, all put into operation between 2001 and 2003. Today, control systems for dynamic hard shoulder running are being operated on more than 250 km of directional carriageways. While several plans for further applications of hard shoulder running on other freeway segments exist, a few former applications were already put out of operation due to the realization of freeway widening. During hard shoulder running, the maximum permitted speed on freeways is 100 km/h. On most sections, hard shoulder running is combined with line control systems including LED signs for displaying variable speed limits as well as road warnings in case of incidents.

In the Netherlands, hard shoulder running has been implemented on freeways since 1996, starting with the A28 near Utrecht. Today, almost 300 km of hard shoulders and so-called “plus lanes” can be dynamically opened for running traffic during peak hours ([CEDR, 2012](#)). “Plus lanes” are dynamic lanes on the left side of the carriageway, which are usually 2.75 m wide and hence narrower

Figure 1 Hard shoulder running on Autobahn A 5 north of Frankfurt, Germany

Figure 2 “Plus lane” on freeway A 12 west of Utrecht, The Netherlands

than normal travel lanes (Figure 2). Both hard shoulder running lanes on the right side of freeway carriageways and “plus lanes” on the left are dynamically opened during peak hours in combination with a speed limit of 100 km/h.

In England, the first hard shoulder running scheme was opened on motorway M42 in 2006. Based on the positive experience with this pilot application concerning its impacts on traffic flow and road safety, further hard shoulder running applications were put into operation on a number of motorways near Birmingham between 2009 and 2011 (Van Vuren et al., 2012). Hard shoulder running incorporates the installation of emergency refuge areas for broken-down vehicles as well as signals and variable message signs on gantries. The maximum speed is restricted to 60 mph when the hard shoulder is in operation. In recent years, hard shoulder running schemes are increasingly replaced by an “all lane running” strategy, which means that the hard shoulder is converted into a normal lane that can be closed by lane control signs in the event of an incident.

In France, hard shoulder running was implemented on the joint section of the freeways A4 and A86 in the east of Paris. A bus-on-shoulder scheme has been applied on freeway A48 north of Grenoble (Princeton and Cohen, 2011). In Flanders, Belgium, hard shoulder running lanes are being operated on freeways E313/E34 and E19 east of Antwerp as well as on freeway E40 from Brussels to Leuven. Further applications of dynamic hard shoulder running in Europe include the Hillerød Motorway M13 north of Copenhagen, Denmark, and the freeway A1 between Morges and Ecublens in Switzerland freeway A1 between Morges and Ecublens in and (CEDR, 2012).

The overall success of traffic-responsive hard shoulder running implementations particularly in Europe triggered their introduction in the United States since 2009, when dynamic hard shoulder use was implemented on Interstate I-35W in Minneapolis, Minnesota. Together with a large number of previous applications of bus-on-shoulder use and static shoulder use schemes, which are still most common, hard shoulder running is applied in more than 16 states. The applications of hard shoulder running in the United States cover quite a variety of different strategies and control systems, including hard shoulder use for buses, passenger cars, and all vehicle types, applications on freeways and arterials, as well as different speed limits and usage criteria. A comprehensive guideline on planning, design, implementation, and day-to-day operation of hard shoulder running was published by the FHWA (2016). This guideline also includes a compilation of existing hard shoulder running applications in the United States.

In South Korea, hard shoulder running lanes were implemented on seven freeway corridors between 2009 and 2013 (Choi et al., 2019). On these corridors, line control systems are used for the dynamic control of the hard shoulder and for ensuring a high level of traffic safety.

Impacts on Traffic Flow and Road Safety

The main objective of implementing hard shoulder running is to provide additional capacity during peak hours, resulting in less congestion and higher travel time reliability. The significant increase of carriageway capacity that is achieved by using the hard shoulder as an additional travel lane often leads to a high benefit-cost ratio of hard shoulder running projects. However, hard shoulder running can only be effective and economically efficient if congestion results from insufficient capacity of the carriageway itself and not from downstream bottlenecks like overloaded off-ramps. Hence, a detailed traffic analysis is useful when considering the implementation of hard shoulder running.

The major challenge of operating hard shoulder running is to maintain traffic safety despite suspending the hard shoulder as an emergency refuge area during peak hours. A high level of traffic safety is usually achieved by sophisticated traffic monitoring and control systems together with a low speed limit during hard shoulder running. The traffic monitoring systems typically include video surveillance of the hard shoulder to check whether the hard shoulder is free of obstacles and broken down vehicles and to be able to close the hard shoulder immediately in case of an incident on the hard shoulder. A number of studies have reported findings on the impact of hard shoulder running on traffic flow and road safety. A selection of relevant publications is summarized in the following.

[Geistefeldt \(2012\)](#) documented experience with dynamic hard shoulder running on two major freeways in the Federal State of Hesse, Germany. Based on loop detector data, it was shown that the capacity of three-lane carriageways can be increased by 20%–25 % if the hard shoulder is used as an additional travel lane during peak hours. The acceptance of hard shoulder running was found to be considerably high among truck drivers. Supporting previous findings, negative effects on road safety could not be determined. By limiting hard shoulder running to those times when the additional capacity of the shoulder lane is needed to prevent congestion together with continuous monitoring of the hard shoulder, the risk for broken down vehicles to be involved in a rear-end collision accident can effectively be reduced due to the fact that any car or obstacle that blocks the shoulder lane immediately causes a traffic breakdown involving a reduced speed level at the incident location. Hence, it was stated that the application of traffic-responsive hard shoulder running combined with dynamic traffic control systems is superior to the permanent transformation of the hard shoulder into an additional travel lane.

[Van Vuren et al. \(2012\)](#) examined the effects of managed motorway schemes around Birmingham considering earlier investigations of the first trialed managed motorway M42 in England. The empirical analysis was based on loop detector data, data from variable message signs, and incident reports from a monitoring period of five years. The comparison of the before and after cases showed that the managed motorway schemes involving hard shoulder running had significant positive effects on the average travel times and their variability as well as increasing traffic throughput. User consultations revealed a positive perception of road users in relation to driver comfort, journey time, and safety. A microscopic traffic simulation of the managed motorway scheme showed that hard shoulder running is particularly beneficial where large traffic volumes exit the motorway. In addition to conventional travel time benefits, an additional 15% of wider economic benefits were estimated, mainly resulting from commuting, business, and commercial trip purposes.

[Samoili et al. \(2013\)](#) analyzed the lane flow distribution with hard shoulder running based on traffic data from radar sensors of a four-lane freeway segment in Switzerland. The results of the lane choice behavior analysis were introduced into a short-term prediction model to describe traffic flow on the section with hard shoulder running. It was shown that opening the hard shoulder leads to an abrupt interruption of the lane flow equilibrium with an immediate transfer of 20% of the right-lane volume to the hard shoulder. An 11% capacity increase and maintenance of speed at 100 km/h were determined as positive effects of the system.

[Kononov et al. \(2012\)](#) examined the relationship between traffic flow and safety parameters to explain the effect of hard shoulder running on traffic safety. The empirical analysis of safety data from four-lane freeways in Denver, Colorado, over a 5-year period revealed that as flow increases, the crash rate initially remains constant until a certain critical threshold of flow parameters is reached. When exceeding the threshold, the crash rate rapidly increases, caused by an increase in density without a notable reduction in speed and resulting small headways that make it more difficult for drivers to compensate driving errors. Regarding the empirical results, it is supposed that crash rates decline during hard shoulder running because of the reduction of traffic density. It is concluded that a positive effect on traffic safety by hard shoulder running can only be reached when density can be reduced under a certain threshold.

[Aron et al. \(2013\)](#) investigated the traffic flow and safety effects of hard shoulder running on freeway A4/A86 in the east of Paris, France. Due to the insufficient capacity of this eight-lane segment carrying an AADT of 280,000 veh/d, hard shoulder running was implemented in 2006. When open to traffic, the hard shoulder operates as an auxiliary lane between the adjacent interchanges. A comparison of accident data from before and after periods revealed a slight, however statistically insignificant, reduction of the number of accidents by 3% during hard shoulder operation, which was attributed to the reduction of traffic density.

[Ma et al. \(2016\)](#) proposed simulation based incident management strategies for freeway segments with dynamic hard shoulder running. The strategies describe the shoulder use options outside peak hours to minimize the traffic flow effects of nonrecurring incidents. To fully use the potential of shoulder running during incidents, an open shoulder section length of 0.5 mile upstream and downstream of the incident location is sufficient. Furthermore, the shoulder can be closed as soon as possible after the incident is cleared, as no improvement in traffic conditions could be determined by a longer opening time. Applying these strategies, the average delay can be reduced by 30%–80% and the total traffic throughput can be increased by 15%–40%, depending on the traffic conditions and the number of blocked lanes.

[Guerrieri and Mauro \(2016\)](#) forecasted traffic flow and safety effects expected by implementing a hard shoulder running system on a 128 km section of freeway A22 in Italy. Safety effects were estimated by means of the Highway Safety Manual methodology ([AASHTO, 2010](#)) based on parameters derived from traffic data. To calibrate the model, real crash data from 3 years were evaluated

and traffic and operation conditions were assumed. According to the model results for motorway A22, no significant variation in the general safety conditions could be determined in the presence of a considerable capacity increase of 35%.

Chun and Fontaine (2017) analyzed the effects of the active traffic management (ATM) system characterized by advisory variable speed limits, queue warning systems, lane use control signs, and hard shoulder running on the Interstate I-66 in Northern Virginia. The authors compared the effects of static hard shoulder running in predefined peak hours before the implementation of the ATM system and dynamic hard shoulder running, which can be applied whenever an increase in roadway capacity was warranted. The investigated ATM system with dynamic hard shoulder running was found to significantly improve the mean travel time and travel time reliability during weekday off-peak periods and on weekends. However, an improvement of travel times in peak periods by the ATM system could not be determined.

Choi et al. (2019) analyzed the safety effects of hard shoulder running on freeways in South Korea. Comparing crash data from 4 years of 22 freeway sections with hard shoulder running, it was found that crash frequencies increased after the implementation of hard shoulder running. Regarding the crash severity, a higher proportion of serious crashes with personal damage was found for two-lane segments compared to three-lane segments. Applying a regression analysis, a positive relationship between the length of the hard shoulder running segment and the crash frequency was determined. However, a statistical relationship between the lane width or shoulder width and the crash frequency could not be verified. Based on the results, it was recommended that hard shoulder running should be avoided on long two-lane freeway corridors.

Conclusions

Hard shoulder running is an effective active traffic management measure to increase the capacity of frequently congested freeway segments by opening the hard shoulder for travel during peak hours. Hard shoulder running is mainly applied in the United States and central Europe. While the first applications in the United States were rather low-tech solutions with static control, including a number of bus-on-shoulder schemes, modern applications of hard shoulder running involve the use of sophisticated traffic monitoring and control systems. Safe operation is provided by continuously monitoring the shoulder and limiting shoulder use to times when the additional capacity is needed to avoid congestion, while the shoulder is still available as emergency lane at off-peak times. A number of scientific studies has proven the positive impact of dynamic hard shoulder running on traffic flow quality, whereas traffic safety is not significantly affected in most cases and can even be improved by the lower traffic density and the reduced extent of upstream congestion.

Introduction

High-occupancy vehicle (HOV) lanes, which have been introduced as an example of managed lane facilities, are reserved for vehicles carrying more than two people, including the driver and are designed and operated to improve travel conditions. The access is sometimes open to motorcycles, transit buses, hybrid, or electric cars regardless of the number of passengers. Commonly referred to as carpool lanes, HOV lanes are usually located on the inside (left) lanes on highways and are identified by signs along the road and painted diamond symbols on the pavement.

The restriction on HOV lanes is varied depending on the amount of traffic and commuter patterns, from 24 hours a day to limited peak congestion periods. When the capacity of the HOV lane is excessive, the lane may be changed to a high-occupancy toll (HOT) lane. The HOT lane can be utilized by vehicles carrying one person for a fee, which may vary depending on the time of day or the level of congestion to maximize the congestion mitigation effect of the HOT lane facility. A HOT lane can be used while the HOV lane is in operation but can also be restricted to use during peak congestion periods. **Figure 1** shows an example of HOV/HOT lane.

Objective of HOV Lane

The main concept of the HOV lane is to facilitate the transition from solo driver vehicle travel to ridesharing, and to eliminate congestion by providing two benefits to the driver: saving time and ensuring travel time (FHWA, 2016). Since HOV lanes carry vehicles with more occupants, more people can be moved during periods of congestion, even if the number of vehicles using the HOV lanes is less than adjacent general-purpose lanes. The concept of HOV lanes gradually developed in the 1970s in the United States and is now being introduced in many metropolitan areas as an effective means of reducing congestion.

HOV lanes also strive to increase the accessibility and reliability for drivers. HOV lanes change our understanding of mode choice behavior where public transit and self-driving are our original mode choices for short-haul land transportation. Public transit generally has low level of accessibility as well as reliability in arrival time. Parking is usually an important issue for self-driving. Parking availability in an acceptable time frame and distance from the destination is uncertain. Ridesharing and HOV lanes deal with these issues with relatively less travel time variability (Javid and Jahanbakhsh Javid, 2018) and need for parking.

Another objective of HOV lanes is to develop a sustainable transportation system, which supports the infrastructure, environment, and public health. HOV lanes are intended to increase the person carrying capacity of highways by encouraging ridesharing and transit ridership. This means a lower level of negative impact from traffic load to bridges and roads as well as less negative health impacts from air pollutants and greenhouse gases (GHGs). Emissions of various toxic gases and GHGs not only influence drivers involved in the congestion, but also impact nearby communities and the planet (Javid et al., 2019).

Figure 1 Example of HOV/HOT lane. Source: <https://ops.fhwa.dot.gov/publications> (FHWA, 2017b)

Table 1 Different classifications of HOV lanes

Classification basis	Types	Description
Traffic flow	Concurrent flow lane	The lane is in the same direction of the general operation lanes, which might be separated or not from the other freeway lanes and typically located in the inside lane or shoulder.
	Contraflow lane	The lane is designated for exclusive use by HOVs users traveling in the peak direction and separated from the off-peak (or opposite) flow by movable barriers.
Separation	Separated lane	The lane is separated from general operation lanes by physical barriers and can be either a one-way reversible or a two-way operation.
	Buffer-separated lane	The lane is not separated with general-purpose lanes by any physical barriers, but set a buffer zone with other lane by using marking on the pavement.
	Nonseparated lane	The lanes operate in the same direction and immediately adjacent to the general-purpose lanes (to the left or right). They are normally less expensive and provide easy access and more conflicts.
Operation condition	Bus lane	Busway lane is usually located on the right side lane so passengers can get on/off the bus safely. Bus Rapid Transit (BRT) lane is set on the left side lane with specific BRT station to reach a very high speed.
	HOT lane	HOT lanes are free to high-occupancy vehicles but single drivers can use them with a fee, which is variable by traffic demand.
	2+ or 3+ Lane	2+ HOV lane can be used by vehicle that have at least 2 occupants (including driver). While, 3+ HOV lane can be used by vehicle with 3 or more occupants.

The final objective of HOV lanes is to save the transportation economy. HOV lanes can encourage ridesharing, which in turn can benefit the transportation system by saving space required for parking and amount of fossil fuel used. Moreover, users who choose to share the ride, can split the fuel, vehicle maintenance, and parking costs.

Different Types of HOV Lanes

Different types of HOV lanes are developed, which can be categorized by traffic flow, lane separation, and operation condition. **Table 1** below summarizes the types of HOV lanes based on different classification basis.

Past and Current Practices

The first HOV lane was introduced in 1969 as a bus-only lane on the Shirley Highway (I-395) from Northern Virginia to Washington D.C. Closely following the bus-only lane in Northern Virginia and Washington D.C. was the bus-only HOV lane in New York-New Jersey's Lincoln Tunnel in 1970. In 1973 the bus-only lane expanded to include any vehicle with four plus (4 +) people, welcoming

Table 2 Examples of HOV/HOT lane facilities in the United States

Example facility	Specification	Explanation
Metro HOV system (Los Angeles, CA)	Concurrent flow lane, Full-time operation, mostly 2+ lanes	A total of 513 miles (823 km) of completed and 132.2 miles (213 km) of planned HOV lanes, make it the largest HOV system in the United States (Caltrans, 2009).
State Route 85 (San Francisco, CA)	Concurrent flow lane, Part-time operation, 2+ lanes	HOV lanes are available only during peak hours Monday through Friday 5 AM to 9 AM, and 3 PM to 7 PM (Metropolitan Transportation Commission, 2020).
I-278 Gowanus Expressway (New York City, NY)	Contraflow flow lane with movable barrier, Part-time operation, 3+	HOV lanes run from the Verrazano Bridge to the Brooklyn Battery Tunnel on the Gowanus Expressway for buses and vehicles weekdays from 6 AM to 10 AM (New York City, 2020).
I-394 Corridor (Minneapolis, MN)	Concurrent flow lane, HOV/HOT lane, combination of movable barrier and buffer-separated, part-time operation, 2+	HOV/HOT pricing varies depending upon the volume and occupancy values of the HOV/HOT lane. One third of the HOV/HOT lane is a reversible lane (offering 2 lanes of travel in the selected direction) operation eastbound 5:00 AM – 1:00 PM and westbound 2:00 PM – 4:00 AM. The rest of the facility is one lane buffer-separated operating eastbound 6:00 AM to 10:00 AM and westbound 2:00 PM to 7:00 PM (Liu et al., 2011).

vans and station wagons (Turnbull, 2005). Vehicle-occupancy requirements for carpools have changed over time and now most facilities use a two-person per vehicle (2 +) carpool designation.

The development of HOV lanes can be summarized as the two stages: The first stage from 1969 to 1990 referred to as the germination period of carpooling lanes, when the construction of HOV lanes dominated highway projects in the 1970s and 1980s lead to over 350 existing HOV facilities in the United States (Turnbull, 2005).

The second stage from 1991 to 2000 is the growth period, this stage involved the cooperation with the environmental protection department, transportation department, and legislation department to formulate a series of transportation measures that help reduce air pollution, such as HOV lanes. California implemented the first HOT lane in 1995 along the US 91 in Orange and Riverside County. HOT lanes were introduced after HOV lanes and are used in a way that employs market forces to improve the use of HOV lanes and collect tolls that can supplement the operations, enforcement, and maintenance costs of the facilities (Turnbull, 2005).

Today, HOV lanes remain the most prevalent form of managed lane in the United States, with lane-miles in service estimated at over 3300 miles (5311 km) (FHWA, 2020a). Today, there are over 350 existing HOV facilities in the 31 metropolitan areas across 20 states. California contains the most HOV facilities at 88, followed by Minnesota and Washington state with 83 and 43, respectively (as of 2009) (Chang et al., 2008). As of 2004 under the Clean Air Vehicle program, the California Department of Motor Vehicles, in partnership with the California Air Resources Board, allows single-occupied vehicles that meet specific emissions standards to use HOV lanes (California Department of Motor Vehicle, 2020). Thirteen other states have similar HOV and HOT lane facility exemptions for vehicles that meet specific emission standards (Alternative Fuel Data Center, 2016). Motorcycles are now also allowed in HOV lanes by federal law because it was safer for cyclists rather than traveling in regular lanes where there are typically stop-and-start traffic conditions, especially during peak travel times. As of 2017, there are 10 operating HOT facilities in either one- or two-lanes in each direction totaling over 100 miles (161 km) in California, Texas, Minnesota, Colorado, Utah, Washington, Florida, and Georgia (FHWA, 2017a). Many states have HOT facility projects in the planning stages as a response to increased congestion in communities. All of the operating projects are conversions of HOV lanes to HOT lanes, although some have extended the HOT lanes. Table 2 below shows some examples of HOV/HOT lane facilities in the United States.

HOV lanes are currently applied in several countries all over the world to solve the traffic problems and provide larger traffic capacity and higher efficiency. Canada has a total of 23 HOV sites in form of 150 km (93 mi) of highway HOV and over 130 km (81 mi) of arterial HOV lanes, in four different provinces. These sites are typically are 3+ HOV lanes, in operation during peak periods (Transport Canada, 2010). The first HOV lane was opened in Greater Vancouver and Toronto in early 1990s (Dixon and Alexander, 2005).

HOV lane was first introduced in Europe in the Netherlands in October 1993. The facility was a 7 km (4.3 mi) 3+ HOV lane with removable barrier and after a year due to low demand was converted to a reversible lane open to general traffic (Schijns and Eng, 2006). A median reversible HOV lane was opened in Spain in 1995 and is still in operation now. Austria opened some of the bus lanes to high occupancy vehicles with at least three occupants in 1998 (Berger, 2002). The United Kingdom opened the first HOV lane facility in Leeds in 1998 as an experimental project and it became permanent later. In 2001 the first ever HOV lane facility in Norway was introduced in the city of Trondheim. This short HOV lane [0.85 km (0.5 mi)] was available for buses, taxis, and vehicles with more than two occupants 24 hours a day (Sandelien, 2000). In New Zealand, HOV lanes are also known as priority lanes. There are a few types of priority lanes usually dedicated to vehicles that have more carriage such as high-occupancy vehicles and trucks.

In 1992, Indonesia implemented the first 3+ HOV lane in Jakarta, known as three-in-one lane, which is from the three-in-one policy (at least three occupants in one vehicle). In South Korea, HOV lanes were introduced in 1994. Only private vehicles carrying

more than six passengers can be access to HOV lanes. Buses also are allowed to use HOV lanes (Kwon et al., 2005). Australia opened their first HOV lane, also known as transit lane in February 1992 on the Eastern Freeway in Melbourne. There are two types of transit lanes called T2 and T3, corresponded to 2+ HOV lanes and 3+ HOV lanes respectively. In China's transportation HOV lane is a new concept. In 2014 Wuxi City, Jiangsu Province offered HOV lanes on Xinyuan Road. The vehicles that have 3 or more occupants can drive on this lane. Then Jinan city followed up and implemented HOV lanes in 2015. In Shenzhen, HOV 2+ has been implemented on Binhai Avenue in 2016. Small vehicles must carry at least two occupants to be qualified to use this lane. This HOV lane can be just operated on weekdays' peak commute time, which is from 7:30 AM to 9:30 AM, and from 5:30 PM to 7:30 PM in China. After 4 months of operation, the Shenzhen government announced a policy of punishment that the vehicles violating the lane will be fined. Based on the development of HOV lanes all over the world, HOV lanes are most commonly used in the United States and it has the most professional and systematic plan for HOV lanes.

Planning

HOV lanes should allow vehicles to travel at high speeds without the HOV facility being perceived by the public as congested or underutilized. To achieve this, planning criteria differ by state and city, with some states varying entry or operating rules by time of day and others operate their HOV facilities 24 hours a day. In terms of who and what vehicles are allowed to enter HOV facilities during operating hours, motorcycles, mass transit, and vehicles with either two (2 +) or three (3 +) occupants are usually allowed to access the HOV lanes. A higher requirement for number of occupants will result in more ridesharing including van sharing and corporate carpooling. If the regional policy makers aim to mitigate emissions and fuel consumption from road transportation certain alternative fuel vehicles can be exempted from the occupancy requirement (Caltrans, 2020). The type and number of lanes allocated to HOVs are also play an important role in their impacts on traffic. The two-lane HOV/HOT facility eliminates low-speed vehicles and reduces traffic on the road. On the ramp, HOV/HOT vehicles are allowed to pass first, thereby improving efficiency. Finally, in order to convert an HOV lane to HOT lane, the level of service, costs, and economic benefits of HOT lanes should be assessed and planned on a case-by-case basis.

Design

HOV lanes can be a part of new highway construction, whole or some parts of highway rebuilding. Generally speaking, HOV lanes, whether one or more, play a role as interior lanes located on the middle of freeway (Cothron et al., 2004).

The HOV lane design process consist of HOV lanes and its auxiliary facilities' design, including HOV direct connector, HOV ramps and local obstructions. Generally, the design considerations need to meet basic principles for highway road design manuals, involving horizontal stopping sight distance, decision stopping sight distance, and vertical clearance. For other requirements, it contains drainage, structural section, and lane width. It still has other options which must be evaluated on a case-by-case basis to satisfy safety, efficiency, and comfort.

Implementation

Public agencies, such as State Departments of Transportation and transit agencies, oversee construction and operation of HOV facilities, often with federal funding support (FHWA, 2020a). Standardization of signboard symbols, pavement marking, and design standards of HOV facilities is essential for proper operation. Due to factors such as multiculturalism and illiteracy, graphic signage is required as much as possible, not letter-based signage, and the internationally recognized symbol for HOV, a slender diamond, is used. If the HOV lane is not sufficiently distinguished from the mixed-flow lane, it may lead to misuse of the lane by an ineligible vehicle. Failure to do so will result in a loss of respect and understanding of the principles of HOV lanes and the potential benefits associated with them, as well as the ongoing issue of violations and enforcement. Therefore, it is very important to distinguish HOV lanes clearly by pavement signs and overhead and roadside signs (Rankin, 1994).

Overhead and Roadside Signs

HOV lane signs should generally follow the federal standards (FHWA, 2009). HOV lane signs should provide the drivers with the entrance location, occupancy requirement, business hours, and cost (for the HOT lane). In addition, the driver needs to be given sufficient time to decide whether to use a controlled lane facility and have safe access to the facility.

For HOT lanes with variable or dynamic pricing, the operator must place at least one variable message sign before every entry point in the managed lane to display fee information so that the user has enough time to decide whether to use the HOT lane (FHWA, 2017a). **Figure 2** provides some examples of HOV lane overhead signs.

Figure 2 HOV lane overhead signs. Source: <https://mutcd.fhwa.dot.gov> (FHWA, 2020b)

HOV Lane Markings

Figure 3 HOV diamond symbol and marking. Source from: <https://mutcd.fhwa.dot.gov> (FHWA, 2009)

Pavement Marking

It is common to draw HOV lanes on pavement marking highways with two parallel white dashed lines to highlight their presence and allow vehicles to join or leave the lanes with dashed lines marking. In addition to characteristic striping, the HOV diamond symbol or the word message HOV is usually marked on the pavement of the lane. **Figure 3** shows the symbol and marking for a regular HOV lane facility. Due to poor visibility from snow and limited durability, the operator cannot rely solely on pavement markings to provide information on HOV lanes. Sometimes, to emphasize the HOV message and alert the lane users, the whole lane is displayed in a different color.

Performance Monitoring

The State DOT in which the HOV facility operates is responsible for monitoring its performance and writing their own procedure and methodology for determining if the operational performance of an HOV facility is degraded (FHWA, 2016).

Programs are established to determine if HOV facilities are meeting its objectives and to monitor and evaluate the performance of HOV facilities. The results of the performance evaluation provide the basis for revising the HOV system operation in order to make improvements. Evaluating HOV facilities involves examining safety, vehicle volumes, level of service, impacts on the movement of people (i.e., how many people use the lane), modal shifts (i.e., how many people alter their travel behavior to use the HOV lane), reliability, travel-time savings, and the impact of the ecological environment (FHWA, 2016). There are minimum performance measures, such as average operating speed that must be met by each HOV facility.

Benefits and Costs

The way how HOV lanes restriction reduces congestion is to encourage carpooling and increase the people-moving capacity of the freeway system. HOV lanes can also increase the congestion on other non-HOV lanes, which may accumulate the overall delay on the road and make the time for congestion disappearance longer. The research on the effectiveness of HOV lanes towards reducing congestion should be positive but sometimes could also be limited and it really depends on the specific traffic condition.

The environmental benefits of HOV lane facilities depend on travelers' demand and their travel patterns, and vary significantly across counties and states according to population density (Javid et al., 2016). A recent research (Javid et al., 2017) found that the greatest projected reduction of air pollutant emissions from HOV lanes development are within areas of relatively high population density at the United States, this would mean that introducing HOV facilities in order to reduce emissions would be most effective in California and east coast states, and least effective in northwest Great Plains.

In addition to the advantages of HOV lanes, the advantage of HOT lanes over HOV lanes is that they allow single-passenger cars to pay for use, and revenue can be generated while increasing HOV lane utilization. With the conversion of HOV to HOT lanes, the number of vehicles on general purpose lanes is reduced and they will be safer with the improved driving environment (Cao et al., 2012). It seems that HOT lanes can be widely promoted and used. However, this is unreasonable because the HOT lanes allow single-passenger use, which is contrary to the original intention of the HOV lanes to promote ridesharing. Therefore, in order to fully and rationally use the HOV and HOT lanes, it is necessary to find a balance between carpooling and congestion pricing (Konishi and Mun, 2010).

The average cost of adding lanes in urban areas, depending on where they are planned, is about \$10 million per lane-mile (\$16 million per lane-km) (FHWA, 2020a). Construction, design engineering and admin, and capital cost for operations are major HOV/HOT related costs. Unlike HOV lanes, HOT lanes require the installation of multiple access points because of the exchange of tolls, and a large amount of money is required for communication facilities (FHWA, 2007). To justify these additional costs for the construction and operation of HOV lanes, especially HOT lanes, the delay saving and toll revenues must be sufficient.

Enforcement

Public awareness and enforcement are key in maintaining the effective and successful operation of HOV and HOT lane facilities. HOV enforcement programs aim to deter possible violators and promote the safe and efficient use of HOV lanes (FHWA, 2016). All HOV facilities are monitored by state or local police officers to enforce the HOV lane requirements and to do this, officers must visually confirm whether the number of passengers in each vehicle meets the minimum requirements. Some states have programs that add self-enforcement by encouraging commuters to report HOV lane violators to the police (FHWA, 2020a). If found violating HOV facility requirements by enforcement officers, violators can be cited or re-directed back into the general-purpose lanes. Fines accompanying citations vary from state to state and depend on the number of citations previously received by the violator. For example, the minimum HOV violation fine in California is \$490, and the maximum fine for first offenders in Georgia is \$75 (Caltrans, 2020; GDOT, 2020).

As technology advances and improves, State DOTs may move toward automated HOV lane enforcement systems for user compliance. Vehicle Passenger Detection systems, which use video analytics to determine the number of occupants in vehicles, may take the role of police officers for enforcing HOV facility regulations.

Acknowledgment

We are grateful to Ms. Desiree James and Mr. Takuya Marui, University of Southern California graduate students, for their constructive input, which helped to improve the quality of the manuscript.

Introduction

Traffic congestion is one of the major issues in most of the urban areas in the world. FHWA states that peak-period trips take an average of about 7% longer in United States (TCR, 2005). Based on global traffic congestion index, Mumbai and Delhi in India, Moscow and Saint Petersburg in Russia have been assigned top most ranks among most congested cities of the world (McCarthy, 2019). The congestion mitigation should be a major concern of traffic engineers and transport planners as it contributes to the accidents, environmental pollution and fuel consumption. The recent statistics by WHO shows that 1.35 million road traffic deaths occur every year globally and there is an increasing trend in the fatality due to accidents (GSRORS, 2018). Road transport is estimated to be responsible for up to 30% of particulate emissions (PM) in European cities and up to 50% of PM emissions in OECD (Organization for Economic Cooperation and Development) countries and accounted for about 23% of global carbon dioxide emissions in 2010. Low- and middle-income countries suffer disproportionately from transport-generated pollution, particularly in Asia, Africa and the Middle East (HSD, 2000). In order to reduce traffic congestion, imparting physical changes on existing roadway facilities (such as road widening, construction of additional lanes) in most of the metropolitan cities is difficult due to the space constraints. Under these circumstances, traffic management techniques such as lane management help traffic engineers and policy makers in dealing with traffic congestion on roadways.

A managed lane facility is one that increases roadway efficiency by implementing various traffic control and management strategies. Reversible lanes (also known as contraflow lanes) are one of the strategies applied to the managed lanes. A reversible lane or roadway is defined as one in which the direction of traffic flow in one or more lanes or shoulders is reversed to the opposing direction for a temporary period of time (GPDOERLS, 2010) as shown in Fig. 1.

Reversible lanes change the directional capacity of a roadway to accommodate peak directional traffic demands. Implementation of reversible lanes does not require extra space or alterations in the geometric features of the roadway. The reversible lanes can be designed and operated with the help of control signs or movable barriers which help the driver to negotiate easily.

Reversible lane operation was found to be first applied in 1928 on 8th Street in Downtown Los Angeles, known as off-center lane movement (GPDOERLS, 2010). Three lanes were assigned for eastbound travel and one lane was for westbound traffic during morning. This was reversed for the evening with three lanes westbound and one lane eastbound. In 1937, this operation was implemented along six miles of Wilshire Boulevard in Los Angeles which was found to be successful. One of the latest reversible lanes implemented in Tyvola road in Charlotte, North Carolina is shown in Fig. 2.

The next section focuses on warrants for reversible lanes. Section State-of-the-Art reviews the state-of-the art on reversible lanes under ordered and disordered traffic conditions. Advantages and disadvantages of reversible lanes are discussed in Section

Figure 1 Reversible lane operation (A) Reversible-flow median lane separated (B) Reversible lane separated by Pylons by concrete barriers. *Source: Adapted from (GIML, 2016)*

Figure 2 Reversible lane on the lions gate bridge in Vancouver, Canada (Frejo, 2015).

Advantages and Disadvantages of Reversible lanes. Operational and safety issues of reversible lanes are provided in Section [Operational and Safety Issues of Reversible Lanes](#). The discussion on reversible lane control is presented in Section [Reversible Lanes Control](#) followed by conclusions and directions for future research in Section [Conclusions and Directions for Future Research](#).

Warrants for Reversible Lanes

The justification or warrants for providing reversible lanes given by various organizations are discussed in this section:

AASHTO Green Book

These manual states that reversible operations are justified when “65% or more of the traffic moves in one direction during peak hours” (APGDHS, 2001). It also suggests that a six-lane street with directional distribution of approximately 65%–35%, four lanes can be operated inbound (toward CBD) and two lanes outbound.

ITE (Institute of Transportation Engineers)

This organization although does not offer specific warrants, suggest a combination of criteria and studies that should be evaluated to justify the need of reversible lanes. The four ITE test criteria to determine the need for reversible lanes are as follows (NASEM, 2004):

- The average speed of the freeway should decrease by at least 25% over the normal speed, or there should be a noticeable backup at signalized intersections leading to vehicles missing one or more green signal intervals (i.e., demand should be greater than the capacity of the freeway)
- The traffic congestion problem under investigation should be both “periodic and predictable”
- The ratio of a major (predominant traffic) to minor traffic count should be at least 2:1 and preferably 3:1. Otherwise, the installation of a reversible lane could be the cause of a new traffic problem on the minor-flow side of the freeway
- The reversible lanes must be designed with adequate entrance and exit capabilities in addition to providing easy transition between the normal and reverse flow lanes. Otherwise, the reversible lane could be the cause of bottlenecks and other traffic problems in addition to the existing traffic congestion.

ITE provides few other guidelines to ensure the need of reversible lane implementation. Reversible lanes are desired in the locations where, the traffic studies show the following inferences:

- Lack of adequate adjacent side streets (not possible to implement one-way operation)
- A high proportion of commuter traffic is found that desires to traverse the area without turns or stops
- No other acceptable alternative improvement measures are possible, such as widening an existing facility or constructing a parallel roadway on a separate right-of-way due to right-of-way limitations and space constraints.

FHWA (Federal Highway Administration)

FHWA (Turnbull and Capelle, 1998) suggests a directional split of 60/40 as a threshold for the level of traffic imbalance needed to warrant a reversible facility.

State-of-the Art

This section focuses on the state-of-art studies related to evaluation of reversible lanes using simulation and optimization, field implementation, operational, and safety issues of reversible lanes under ordered and disordered traffic conditions.

Ordered Traffic

Simulation and Optimization

Zhou and coworkers (Zhou et al., 1993) proposed an intelligent-self learning dynamic optimal reversible lane control system for the George Massey Tunnel in southern Greater Vancouver. An optimization algorithm was developed to obtain real time optimal reversal schedule based on the predicted demand. A fuzzy modeling algorithm was developed to sort the real time data to identify the best matching pattern and a self-learning mechanism was used to modify the predicted demand incrementally. Meng and coworkers (Meng et al., 2008) developed a variation of genetic algorithm that embeds with microscopic traffic simulation model to find an optimal reversible lane configuration solution. Bi-level programming model was developed, where the upper level problem is a binary integer programming formulation that aims to minimize the total travel time of a study area and the lower level problem is a microscopic traffic simulation model (PARAMICS) simulating the dynamic reaction of the drivers which is caused by a reversible lane configuration scheme. A case study in Singapore is carried out to evaluate the proposed methodology. A bi-level programming model was presented by Wu and coworkers (Wu et al., 2009) in which the upper level model is to minimize the total system cost and flow entropy, while the lower level is a stochastic user equilibrium assignment with an advanced traveler information system. The objective function of the lower level model is to minimize the users’ travel cost under the stochastic user assignment with an ATIS. Result shows that, by adopting reversible lanes and an ATIS, the total system cost is greatly reduced. A framework for dynamic lane reversal was developed by Hausknecht and coworkers (Hausknecht et al., 2011), in which the lane directionality of reversible lanes is updated automatically with the information of instantaneous traffic conditions recorded by traffic sensors. Experimental results for assumed network indicate that reversible lanes provide increased network efficiency and dynamic lane reversals provide more benefit in travel time reduction inside the network. The study conducted by Liu et al. (2011) made an attempt to develop an optimization model using road impedance function (BPR function by FHWA) to determine the number of lanes to be converted for reversible use. The directional distribution factor of 2/3 was recommended for the criteria to activate the reversible lane system. A

macroscopic model has been presented by Frejo et al. (2015) for dynamic operation of reversible lanes. Two types of dynamic controllers were developed for lane control which involved, a logic based controller which works based on congestion lengths and a discrete model predictive control (MPC) which reduces the total time spent (TTS) of the network. The model and control algorithms were simulated and tested using loop detector data at SE-30 freeway Seville, Spain. The MPC system was found to be advantageous in reducing TTS on the network.

Implementation, Operation, and Safety

A unique solution that was developed in Utah to improve the efficiency of a major east-west urban arterial using existing road infrastructure was presented by Guebert et al. (2010). State Route 173 (urban arterial road) in Salt Lake has a week day traffic of 73/27 split in the morning peak hour and a 39/61 split in the afternoon peak. The recommended solution was to implement a reversible lane system that could shift the two-way left turn lane to accommodate lane reversal at different times of the day.

Operational and safety impacts of reversible lanes were analysed by Ma and Aden (Ma and Aden, 2011) on a reversible lane segment on Connecticut Avenue, NW. The reversible lane segment operated with four inbound (southbound) lanes and two outbound (northbound) lanes during the morning peak hours (7:00 am to 9:30 am) and it was reversed during the evening peak hours (4:00 pm to 6:30 pm). Three lanes are open to traffic in each direction at all other times. The peak direction accounted for 70 percent of the bidirectional traffic volume.

The effects of the reversible lane system on traffic flow and road safety was studied at a freeway work zone in Frankfurt, Germany by Waleczek et al. (2016). The road-safety analysis shows an increase of crash rates during road works. But, only 10% of the total number of crashes and no severe crashes could be linked to particular features of the reversible lane system. The evaluation study showed that, at the analyzed work zone, estimated travel time losses of 4,00,000 veh/h could be saved during two months of road works by the application of the reversible lane compared with a reduction of permanent lane in one direction.

Disordered Traffic

Simulation and Optimization

A dynamic control strategy and switch method for the operation of reversible lanes on freeways, bridges, or tunnels was designed by Ma et al. (2018) for both one and multiple reversible lane with continuous flows. Average delay of all the vehicles on the road were used to develop operation models of reversible lanes under different states. Enumeration algorithm were applied to solve the optimization models. The proposed methods and models were simulated and tested using data of a five lanes bridge in Guangzhou, China, via microscopic traffic simulation. The results show that the proposed method and models were able to reduce the delay and congestion. Kotagi and Asaithambi (2019) evaluated reversible lane operation using a microscopic simulation model developed specifically for urban undivided roads in disordered traffic. Results showed an increment of 568 veh/h during morning peak hour and 396 veh/h during evening peak hour after implementing reversible lanes.

Implementation, Operation, and Safety

Traffic conflict characteristics at a temporary reversible lane (1.4 km with 6 lanes going in two directions) at Huangpu Road (from Lingyuan Street to Gaoneng Street) in Dalian, China were investigated by Cao et al. (2014). Issues with temporary reversible lane such as inadequacy of control facilities, more number of conflicts during initial stage of direction changing and a lower utilization rate of temporary reversible lane were reported from the study. A case study on reversible lanes traffic controlling in Beijing, China was presented by Wang et al. (2014). The study stretch from Chedaogou Bridge to Sijiqing Bridge (Zizhuyuan Road) is 1.8 km long and 24 m wide (6 lanes) which is bidirectional was considered to design and implement the reversible lane operation. To implement reversible lane channeling, the central isolation barrier was moved and the main traffic lane was divided into 7 lanes, of which the most central lane is reversible lane. The estimated width of the reversible lane is 4 m with other traffic lanes being 3.25 m wide. The reversible lane operation was carried out every day between 6 am and 12 pm toward the city and for the rest of the day, the travel direction was away from the city.

Advantages and Disadvantages of Reversible Lanes

Major advantages of reversible lanes are decreased turbidity in adjacent flows, greater efficiency in toll collection for priced facilities and improved public perception of the system's efficiency (ADRL 2010). The other advantages of reversible lanes are listed below

- Reversible flow facilities are most suited for limited access through travel
- Efficient for longer distance trips
- Separation from normal lanes improves flow
- Maximizes V/C ratio utility by putting lanes in the direction having higher flow
- Potentially less expensive when compared to bi-directional facility
- Requires less right-of-way in general
- Provides air quality improvements by reducing congestion
- The construction period is lesser.

The disadvantages of reversible lanes when compared to normal bidirectional lanes are:

- Not well known to drivers and involves complex operations
- Requires studies to determine optimal hours of operation
- Less suited to short trips
- Requires additional signage and gates to prevent access to vehicles during off hours and needs more enforcement
- Transference onto a radial corridor may not be possible
- Variations in hours of operation can complicate accessibility
- Air quality benefits may not be significant in locations with lower directional splits

Operational and Safety Issues of Reversible Lanes

Reversible lane facilities though reduce congestion on peak hours, they may lead to some issues in traffic movement which trouble the commuters and sometimes the residents of the area. A study conducted in the United States ([Ma and Aden, 2011](#)) describes few issues associated with reversible lanes:

- The reversible section has a higher percentage of crashes during the hours of reversible operation than during regular operation. The major types of crashes that may occur on reversible roadways are sideswipe and head-on collisions.
- The reversible lanes are also not very pedestrian friendly due the absence of medians which increases pedestrians' exposure to vehicles when crossing the street. Also, reversible lanes make the crossing maneuver somewhat confusing for pedestrians, especially in areas that have large number of unfamiliar pedestrians.
- Reversible lanes can cause discomfort to the residents in the surrounding especially at those time periods when reversible lanes are used for one-way operations.

An analysis carried out on conflict analysis at temporary reversible in Dalian, China investigated the conflicts before and after the change in direction of movement on the reversible lane ([Cao et al., 2014](#)). The study stated that the traffic conflicts were more on the reversible lanes than the normal lanes. More number of conflicts are observed in the initial stages of direction change due to the adverse driving behavior due to the switching of movement directions.

A study conducted at a freeway work zone with reversible median lane in Frankfurt, Germany ([Waleczek et al., 2016](#)) showed that the marking of lane separation at the beginning of the reversible lane is necessary to ensure road safety. The study also stated that, in order to prevent crashes due to lane changes the barriers can be provided to separate lanes at both the sides of reversible lanes.

Transportation Association of Canada ([GPDOERLS, 2010](#)) suggests some unique requirements of reversible lane operations to address the issues associated with them:

- In case of reversible lane systems the through traffic is always given priority and hence turning movements are mostly prohibited along the roadway. Hence, there must be sufficient analysis made prior to the implementation of lane reversal so as to plan the provision of turning movements.
- The provision of pedestrian crossings along the reversible lanes should be limited to avoid the impact of lane reversal on pedestrians.

Reversible lanes do not contribute significantly to increased frequency or severity of accidents and additional care could be taken such as complete infrastructures, electronic information board and signal control ([Liu et al., 2011](#)). The properties of the barriers such as impact resistance, are also important in reducing the crash severity.

Reversible Lanes Control

The major methods of guiding and controlling traffic at the entrance, exit, and within reversible segments are roadway signs, signals pavement markings, and physical separation.

Signs and Signals

The earliest reversible segments were controlled only by signs and sometimes involved traffic enforcement personnel. The recent standards for the design and placement signs for reversible roadways are contained in the MUTCD 2009 ([MUTCDSH, 2009](#)). The use of both roadside ground-mounted signs and overhead signs for use on reversible arterial facilities is given in [Table 1](#). If overhead signs are used, they should be located at intervals not greater than 400 m (0.25 mi). The height of the overhead signs from the pavement grade should not be more than 5.8 m (19 ft). Where more than one sign is used at the termination of a reversible lane, the spacing between them should be at least 75 m (250 ft) apart. Longer distances between signs are suitable for roads with speeds over 60 km/h (35 mph), but the separation should be within 300 m (1,000 ft).

Lane-use control signals (refer [Table 2](#)) are used to indicate which lanes of a reversible roadway are available (or not available) for use in a particular direction and also, which lane might be in the process of changing operation ([NASEM, 2004](#)). MUTCD 2003

Table 1 Signs used in reversible lanes (MUTCDSH, 2009)

Symbol/word message	Meaning
Red X on white background	Lane closed
Upward pointing black arrow on white background	Lane open for through travel
Modified black left/through arrow on white background in case of permitted left turns	Lane open for through travel and any turns not otherwise prohibited
Black two-way left turn arrows on white background and legend ONLY	Lane may be used only for left turns in either direction (i.e., as a two-way left turn lane)
Black single left turn arrow on white background and legend ONLY	Lane may be used only for left turns in one direction (without opposing left turns in the same lane)

Table 2 Lane-use control signals used for reversible lanes (GIML, 2016)

Symbol	Name	Meaning
	Steady Downward Green Arrow	Permitted to drive in the lane
	Steady Yellow X	Prepare to vacate the lane
	Steady Red X	Not permitted to use the lane

**Figure 3** Reversible lane marking. Source: Adapted from (MUTCDSH, 2009).

(MUTCDSH, 2003) offers guidance on horizontally and vertically locating those devices along the roadway, stating that shall be clearly visible for 700 m (2,300 ft) at all times under normal atmospheric conditions, unless otherwise physically obstructed.

Pavement Markings

Pavement markings with words and symbols are considered supplementary to signs. MUTCD 2009 (MUTCDSH, 2009) suggested the following reversible lane pavement markings: “two normal broken yellow lines [on each side of the lane] to delineate the edges of lane in which the direction of travel is reversed” (refer Fig. 3). MUTCD 2003 (MUTCDSH, 2003) gives guidance on the use of raised pavement markers substituting or supplementing the pavement markings, including their lateral and longitudinal spacing.

Physical Separations

Various types of barriers have been used for reversible lane segments. A more innovative barrier system for reversible roadways is the movable barrier. Movable barriers have been used both on permanent bases for roadways and bridges and on temporary bases

Table 3 Summary of reversible lane control (GPDOERLS, 2010)

Control facility	Arterial (at-grade, minor or unrestricted access)	Freeway (limited access)
Signs	- Needs to be well signed to provide clarity to drivers; both main street and side street signage is recommended - Consider use of Dynamic message signs (DMS)	- Needs to be well signed to provide clarity to drivers - Consider use of DMS
Signals	- Green “down arrow”; flashing red “X”; solid red “X” - Where reversible lane signals are closer to intersection traffic signals, consideration should be given to turning off the green arrow when a red signal is displayed for that approach - Spacing is every 75 m or to fit situation - Signals should be placed such that they do not conflict with intersection traffic signals (not within 35 meters) - Drivers must be able to see at least 2 signal sets at a time in their direction of movement	- Green “down arrow”; flashing red “X”; solid red “X” - Drivers must be able to see at least 2 signal sets at a time - Only signals at transition zone may be needed in case of barrier separated reversible lanes
Pavement markings	Broken double yellow line dividing directional flows for different times of day	- Physical separation is preferred over lane markings to separate directional flows in freeway reversible lanes - Where physical separation is impractical, speed restrictions should be considered in conjunction with broken double yellow dividing lines
Separation barriers	Portable or none	- Barrier need to be considered to separate opposing traffic - Fixed or moveable concrete barriers have been used in different jurisdictions

within construction zones where unbalanced directional flows are experienced (GPDOERLS, 2010). The width of the buffer varies, and some are much wider and incorporate pylons or other channelizers to separate traffic flows (GIML, 2016).

Table 3 gives the summary of reversible lane controls to be adopted in different types of facility.

Conclusions and Directions for Future Research

Reversible lanes (contraflow lanes) is one of the traffic management measures suggested for reducing the traffic congestion on a roadway facility. In this chapter, warrants for reversible lanes suggested by few organizations like AASTO, ITE, and FHWA are discussed. Literature review shows that there are only few attempts made on the study of reversible lanes particularly on warrants, scheduling, operational, and safety issues. The advantages and disadvantages of reversible lanes and also, control of traffic on reversible lanes using different methods are explained in detail.

Further scope of the work are as follows: There are no clear warrants available for justification of reversible lanes for different countries. Standard warrants common for all the countries are difficult to formulate since the traffic conditions vary from country to country. However, few warrants (e.g., number of lanes, directional split) can be considered common for all the countries and country-specific warrants (e.g., traffic composition) can be added further based on local traffic conditions. Hence, there is a need for more number of studies to bring out the warrants for reversible lanes.

There are no rigorous studies available on finding optimal number of lanes and also, on optimal scheduling and operational hours of reversible lanes. More number of studies should be attempted to optimally utilize the reversible lanes both spatially and temporally using simulation and optimization techniques.

Real-time traffic management system can be employed to control traffic congestion more efficiently with the help of Internet of things (IOT) and cloud computing. IOT is connecting different application devices to one other through internet with the use of CCTVs, sensors and smart devices, which able to transmit a wide variety of data, location, movement, environment, etc. This system will be helpful to change the operational hours of reversible lanes intelligently according to traffic density, directional split on the roadway. It would assist road users to obtain prior contextual guidance with the help of dynamic message signs to avoid potential hazards on the reversible lanes.

In most of the developing economies, traffic is disordered in nature. In addition to that, traffic congestion is the most important problem due to increase in traffic volume with presence of side frictions like on-street bus stops, pedestrians, on street-parking, encroachments, etc. The extension of roads will not be sufficing to mitigate congestion. So, the available road width has to be effectively managed by implementing traffic management measures like reversible lanes. The existence of such lanes under disordered traffic conditions is hardly seen. Hence, there is a need for in depth study on reversible lanes in developing economies.

Overview of Electronic Toll Collection

Electronic toll collection, often denoted as “ETC,” is a system capable of electronically charging a toll to a vehicle or its user by automatic identification and classification of vehicles on a tolled facility such as road, tunnel, or bridge.

Traditionally, toll was collected manually by cash, in some cases by token, pre-paid card, credit card, etc. Automatic payment machine was installed later in some cases instead of manual operation. Evolution of cashless and automatic transaction had contributed to reduce necessary time of transaction and labor costs. However, all of these payments require all vehicles to completely stop for a transaction at a tollbooth. Such conventional systems are not efficient for many reasons (Hensher, 1991):

- Each vehicle has to slow down, stop and wait for the transaction in toll plaza, which forces traffic flow to slow down, and results in congestion if amount of traffic comes in. Thus drivers incur delay and get frustrated. Furthermore, exhaust gas is emitted due to deceleration and acceleration.
- Necessary number of tollbooths (especially in open-toll system where tollbooths are on certain sections of roads) in toll plaza is typically larger than the number of traffic lanes, because traffic capacity of tollbooths is significantly lower than other general sections. That requires considerably high infrastructure costs including land requirements.
- Manual toll collection requires amount of labors, which is costly not only for their wage but also for more infrastructure, such as barrier or underground passage around tollbooths in order to protect the labors.
- Applicable tolling scheme becomes much limited. It is hard to apply complex tolls distinguished by time of day, type of vehicles, laden weight, distance traveled for example.

Electronic toll collection uses information communication technology (ICT) to automatically collect tolls without stopping vehicles at tollbooths, directly solving associated problems of congestion, delay, emissions, etc. It can reduce necessary infrastructure and land space in many cases, as well as reducing the labor cost. For example, in Norway, it was shown that a lane with electronic toll

Figure 1 Types of AVI systems.

collection could handle three times of the traffic volumes handled on the manual lane, and the cost with full electronic collection could be between 33% and 50% of the one of a manual system (Hensher, 1991).

The cost to implementing and managing the electronic toll collection system depends on the case, but some empirical evidences have been demonstrated that it is more cost effective than manual operation. Thus, it has been widely spread and one of the most successful use case of the intelligent transport systems (ITS) around the world, since 1989 when it was fully deployed in motorways in Italy for the first time. According to the survey on the 43 different private and public entities involved in toll road operations across the Americas, Europe and Asia, 91% of the subject entities use some form of the electronic toll collection, and furthermore 27% uses only the electronic toll collection system and without any other alternatives as of around 2014–15 (KPMG International, 2015).

One of the most important advantage of the electronic toll collection is the flexible applicability to variety of tolling scheme. It makes it possible to differentiate tolls by time of day, type of vehicles, laden weight, distance traveled using an appropriate component in in-vehicle device, roadside equipment and back office. Because of this advantage, the system is currently considered as more widely applicable means of road pricing, thus sometimes called as the electronic fee collection (EFC), in which tolls are charged not simply on the individual routes or sections but rather inside the certain area such as city center (i.e., urban road pricing) or depending on traffic flow conditions (i.e., congestion pricing).

Technologies

There are four major components for the electronic toll collection: vehicle identification, vehicle classification, transaction processing, and violation enforcement. Currently, a variety of the technologies used for each component can be observed in different systems by country, state, or road operator.

Vehicle identification, abbreviated as "AVI" (Automated Vehicle Identification), is the most crucial process in electronic toll collection. It is a process of identifying the subject vehicles automatically. Basically, there are three different types of AVI: systems that uses dedicated roadside equipment, autonomous systems that uses satellite positioning, and camera detection system, as shown in Figure 1. The first two systems require onboard transponders.

The systems with dedicated roadside equipment are one of the most conventional and widely applied systems where subject vehicles are identified by a communication between onboard transponder located in the vehicles and roadside antennas when the vehicles pass through. Dedicated Short Range Communication (DSRC) has been used world widely, and Radio Frequency Identifier (RFID) is also getting popular in many countries. Some systems use infrared ray for the communication instead of these radio wave. Systems using DSRC and RFID are illustrated in Figure 2. In general, DSRC can achieve higher communication speed, larger transmission capacity and higher accuracy than the other systems, and enable bidirectional communications between onboard transponder and roadside antenna. In other words, both vehicle-to-infrastructure (V2I) and infrastructure-to-vehicle (I2V) communications are possible with DSRC. Thus, it is possible to expand the functions of the onboard unit using the same transponder (e.g., traffic information can be provided from roadside antenna to vehicle). On the other hand, RFID can be installed relatively cheaper because it requires only a small RFID tag for onboard transponder unlike the mechanical onboard unit for DSRC. Therefore, it is easier to introduce at lower cost, but the back office has to process much more task such as matching of the entry and exit data than the DSRC system where many tasks can be locally done by roadside equipment.

Apart from the above-mentioned systems, autonomous systems use satellite positioning for AVI, not requiring dedicated roadside equipment, as illustrated in Figure 3. This type of systems localizes the vehicle using Global Navigation Satellite System (GNSS) and find its position on the map contained in the onboard unit. Here, additional sensors such as gyroscopes, odometers, and accelerator meter are combined in many cases. Then, as the map in the onboard unit include geographic information of tolled area, vehicles can be identified when it enters and exit the tolled area, and these information is sent to the back office that makes payment transaction via cellular network. As mentioned, this system does not require dedicated roadside equipment for AVI, thus infrastructure cost can be lower. However, as means of violation enforcement, roadside equipment such as DSRC antenna or cameras are still often used for compliance checking. Great advantage of the autonomous systems is its wide applicability to various types of tolling scheme, such as distance-based tolls, route-based tolls, urban area pricing, zone pricing, etc., as its vehicle identification can be done continuously.

Automatic Number Plate Recognition (ANPR) is another way of AVI where roadside cameras capture images of vehicles passing through toll plazas, and the number plates of the vehicles are extracted through image recognition. This does not require any

Figure 2 Systems using (A) DSRC and (B) RFID.

Figure 3 Autonomous systems using GNSS.

onboard transponder thus allows users to use toll roads without any preparation (i.e., purchase of onboard unit or RFID tag). However, at this moment, accuracy of fully automatic recognition is not as high as other systems. Manual review can be supplementary incorporated in order to improve the accuracy, but that requires additional labor costs. Privacy concern and jurisdictional problem are also issues which often raises for ANPR in many countries.

As mentioned, each system has advantages and disadvantages on different aspects such as accuracy, flexibility to tolling scheme, possible expansion of systems, interoperability, initial and running costs for road users as well as those for road operators. Thus, it is important for countries, states, or road operators to select the system based on their needs and requirements. New systems with new technologies are also emerging in some countries. Types of charging technologies (mainly about vehicle identification) and tolling schemes (in other words, charging policies) in different countries are listed in [Table 1](#).

Vehicle classification is necessary when different toll rates are charged for different types of vehicles. The technology is closely related to vehicle identification (AVI), as the simplest method is to store the vehicle type information in onboard transponder and send it together when vehicles are identified. Another way is to use the sensors, such as inductive sensors, laser sensors, etc. Weigh-in-motion (WIM) is a new technology which can capture the axle weight and gross vehicle weights when vehicles drive over the measurement site. Using this technology, it is possible to measure the weight without requiring vehicles to stop. WIM is often used to enforce a law on truck overloading, and further started to be utilized for toll-by-weight in China ([Hang et al., 2013](#)).

Effect on Traffic on Toll Roads

As mentioned, one of the most important benefit of electronic toll collection is reduction of congestion and associated negative impacts such as delay and emission. Several indices have been used to evaluate the effects of electronic toll collection on the

Table 1 Types of charging technologies and policy (JSAE, 2019)

Charging policy		Financing of road infrastructure			Traffic management	
		Toll road (ETC)	Inter-city road (Heavy goods vehicle charge)	Every road	Urban road (Rush hour charge)	Inter-city road
ANPR: Identification plate scan					London Stockholm	
DSRC		World wide (More than 50 countries)	Austria, Czech Republic Poland, (Slovenia)		Oslo, Bergen, etc. Singapore	
GNSS	Mobile phone network		Germany, Slovakia, Hungary, Belgium, Russia (Bulgaria)		(Singapore)	
	Odometer			USA Toll charge		
	DSRC					Japan Charge by guiding routes
RFID: Electronic tag		North America, South and Central America India, Taiwan, etc.				USA High-speed lane
WAVE: New DSRC		(South Korea)				
WIM: Dynamic load measuring apparatus		China

performance of toll plaza operations through empirical analysis and estimation models development (e.g., Al-Deek et al., 1997; Aycin, 2006; Woo and Hoel, 1991):

- (Traffic) capacity is defined as the maximum sustainable hourly flow rate at which vehicles can traverse a point or a section of a lane or roadway during a given time period. As for a lane with a tollbooth, it can be measured by counting vehicles departing from the tollbooth under saturated condition where queues are present upstream.
- Throughput per lane is the vehicle counted at the downstream of the tollbooth during a period of time. Unlike the capacity, throughput is measured regardless of the upstream queuing condition.
- Service time is the time that a vehicle spends to pay a toll at the tollbooth. Intervehicle time is the time difference between two consecutive departures of vehicles at the tollbooth. It is the sum of the service time and the vehicle headway. These two indices do not include the waiting time in the queue.
- Queuing delay is the time that each of individual vehicles spends in a queue upstream of the tollbooth. This does not include the service time. Average queuing delay is the average, and total queuing delay is the sum of queuing delay over all vehicles in the queue.
- Time spent in a toll collection system includes the sum of the effect of service time and queuing delay.
- Delay or lost time is the additional time experienced by the presence of tollbooths.

As mentioned, in Norway, a lane with electronic toll collection could handle three times of the traffic volumes handled on the manual lane (Hensher, 1991). In the United States, NCHRP (TRB, 1997) reported the capacities of a lane with manual collection and electronic toll collection are 350 veh/h and 1200 veh/h, respectively. Here, the lane with electronic toll collection means the one dedicated for electronic toll collection only, but it is located in the same toll plaza with different types of lanes (e.g., manual lane). The report also mentioned that if a lane with electronic toll collection is physically separated from other types of lanes and allows free-flow operation, which is called as an "express" lane, capacity can be further higher to 1800 veh/h. It is known that such a physical and operational conditions of electronic toll lanes (e.g., separation from manual lanes, presence of the gate, speed limit) affect capacity and operational performance. Another report in the United States by Al-Deek et al. (1997) mentioned that the capacity of a lane with electronic toll collection (not an express lane) was higher than the value shown in NCHRP (1200 veh/h) (TRB, 1997), which is considered due to the absence of the gate at the tollbooth. Furthermore, they reported that the service time, the average queuing delay and the maximum queuing delay could be decreased by five seconds per vehicle, one minute per vehicle and 2.5–3 minutes per vehicle, respectively by the electronic toll collection.

Mixed lanes which allow both manual and electronic payments are also installed in many cases. Performance of the mixed lane is not as high as the dedicated lane with electronic toll collection mentioned above but still higher than the manual lane [e.g., capacity is 700 veh/h according to NCHRP (TRB, 1997)]. It also depends on the proportion of users of the electronic toll collections; the more users pay electronically, the higher the lane performance becomes.

Besides, evaluation of the performance of as a whole of toll plaza often consisting of multiple lanes with different types of toll collections (manual, electronic, mixed, etc.) is also important. Different configuration of lanes may result in different levels of service, because it affects users' lane choice and conflicts between vehicles on the upstream of the tollbooth. It is recognized that adding another mixed lane does not necessarily increase capacity proportionally, because the capacity of the mixed lane depends on the proportion of electronic toll users as mentioned above but it is not known (Aycin, 2006). In general, users of electronic toll collection are likely to prefer the dedicated lane because it can process the queue faster (Al-Deek et al., 1997; Aycin, 2006), but it may also depend on the penetration rate of the electronic toll collection. Therefore, enough consideration has to be made for designing toll plaza.

Figure 4 Systems of ETC in Japan (MLIT Japan, 2012). Source: <http://www.mlit.go.jp/road/ir/ir-council/pdf/7.pdf> (translated by the author)

Case Study in Japan

Japan is one of the few countries where a single universal system of electronic toll collection, which is called as “ETC” system, is applied to all of the toll expressways (controlled-access motorway) in the country. In Japan, research and development for the electronic toll collection had been conducted from 1994 to 1995 jointly by public sectors which are in charge of road construction and operation and private companies such as communication equipment, electric equipment, computer, and car manufacturers. Based on these results and experiments in the test field, the first test operation was done in the actual expressway sections in 1997, and specifications were established and published for the universal system in the country in 1998. In November 2001, it was finally deployed nationwide.

Figure 4 describes a schematic image of the ETC system in Japan. It uses DSRC for vehicle identification and classification, thus vehicle information is stored in the onboard unit and sent to the central office through the communication with roadside antenna. Onboard unit consists of an onboard equipment and a so-called “ETC card”; the former needs to be installed in a vehicle and store the vehicle information such as vehicle type and plate number, the latter is issued by credit card companies and used for payment. This is called as two-piece system, and makes it possible for the persons who are not the owner of the car (e.g., rent-a-car) to pay the fee by inserting his/her own ETC card into the onboard equipment. The onboard units for two-wheelers (i.e., motorcycles) are also sold from 2006.

Because users need to purchase and install onboard unit by themselves, government (i.e., MLIT Japan) and expressway companies put some incentives such as discount or mileage point on road users who buy the onboard unit in an early stage of the deployment. Thanks partly to these promotion, ETC penetration rate, percentage of those who paid their tolls by ETC system among all expressway users, have increased rapidly since its deployment in 2001; it reached above 15% in 2004, 56% in 2006, 83% in 2010, and 92% in 2019 (MLIT Japan, 2019).

As one of the effects of such increase of ETC users, congestion had been drastically reduced. It was reported that the total lost time due to congestion had been decreased with the increase of the ETC penetration rate since 2002; Actually, the total lost time could be reduced into less than one third with the ETC penetration rate of 25% within the first few years on the intercity expressways of east Japan (East Nippon Expressway Co., Ltd., 2020). Although there may be several additional factors for this reduction, we can identify that the introduction of ETC would have contributed so much. As one of the evidence, **Figure 5** shows the comparison of number of traffic breakdowns occurred at the major bottlenecks on expressways by segment type between before and after the deployment of ETC. As shown in the figure, toll plazas had been a major type of bottlenecks in expressway network, as breakdowns had occurred about four thousand times per year which accounts for 30% in total. However, it could be reduced to only sixty times per year which accounts for 0.8% after the introduction of ETC.

From the viewpoint of operational costs, ETC could be cheaper than manual collection, because it could reduce the large amount of labor costs. **Figure 6** shows that in FY2011 when 15% of road users paid manually and 85% of users used ETC, costs spent for manual collection was higher than those for ETC, due to the large amount of outsourcing costs for the manual collection done by labors.

Furthermore, ETC have made it possible to introduce new designs of interchanges with on- and off-ramps where toll plaza must be located between expressways and other highways. Such interchanges conventionally need larger space as illustrated in **Figure 7A**, because they usually require to put tollbooths for different directions into one toll plaza so that they can reduce labors and facility for manual toll collection. However, it became possible to operate unmanned tollbooths with the ETC, and which made it possible to separate toll plazas for different directions and need less space as illustrated in **Figure 7B** and **C**. Conventional interchanges without

Figure 7 Schematic image of (A) conventional interchange, and new interchanges, (B) connected to the mainline directly and (C) connected to the rest area (MLIT Japan, 2012). Source: <http://www.mlit.go.jp/road/ir/ir-council/pdf/7.pdf> (adjusted by the author)

ETC costs 3.5 billion JPY for construction and 90 million JPY/year for maintenance, while new types of interchanges with ETC costs 2.0 billion JPY and 70 million JPY/year respectively as of November 2012 according to MLIT Japan (2012).

As mentioned above, one of the advantages of electronic toll collection is its flexibility of available tolling scheme. Here, one example in Tokyo is the discount for detours which contribute to relief congestion introduced in 2014; when users took longer

Figure 8 Discount for detour using ETC and its effect (MLIT Japan, 2012). Source: <http://www.mlit.go.jp/road/ir/ir-council/pdf/7.pdf> (translated by the author)

detour using ring road (C2, shown by the red line in Figure 8) and avoided from passing through the city center (C1, shown by the blue lines), toll were reduced by 100 JPY for passenger cars and 200 JPY for large vehicles. In order to give such a discount, it is necessary to identify route of vehicles from their origins to destinations, which can be hardly done by manual tolling but is possible by putting roadside antennas on the mainline of the detour route (as shown by purple lines in Figure 8). Right-hand side chart in Figure 8 shows an effect that the through traffic passing on the C1 road reduced and the route share was shifted in about 3%. Besides, flexible tolling scheme like discount in night time, discount for the companies which have frequent use of their vehicles, and giving mileage points for the certain time of day on the certain area have been introduced by utilizing ETC.

In 2014, the upgraded systems which is called “ETC 2.0” was deployed in Japan. The new types of onboard units can record vehicle trajectory using GPS and upload it to back office via roadside antennas along expressways and national highways using DSRC. It became also possible to provide area-wide road traffic information from roadside antennas to onboard units.

Traffic Management with Electronic Toll Collection

Road pricing has been considered as an efficient way to manage traffic demand. Due to the advantage of flexibility of tolling scheme, electronic toll collection has enabled to introduce road pricing with more choices of the charging objective, charging schemes, and charge levels.

One successful example is found in Singapore. Singapore introduced cordon-based road pricing named as Area Licensing Scheme (ALS) in 1975, which charged drivers who entered downtown in order to manage traffic demand. It was upgraded into so-called Electronic Road Pricing (ERP) using DSRC system of electronic toll collection. In this system, tolls are varied by time of day and by location of the gantry with DSRC antennas. The rate of tolls is reviewed every three months so that the average travel speeds on the roads can be maintained at the certain level (i.e., 20–30 km/h on city roads and 45–65 km/h on expressways). Singapore is currently developing the next generation road pricing system based on GNSS technologies, and expects to introduce around 2020. (ITF, 2019)

With the development of connected and automated vehicles and infrastructure, importance of traffic management using such technologies will be paid by much more attention in the future. Accordingly, electronic toll collection is expected to be evolved and integrated into other ITS systems which realize more efficient and sustainable transportation.

Introduction

Transportation is a vital element in any community endeavor to strive and progress. Often, it is a means to an end, that is, it is an activity that connects two different functions or places such as from homes to workplaces, or homes to schools. Efficiency and safety are important attributes of transportation systems although other attributes such as comfort, cleanliness and environmental friendliness have also been considered important. Efficiency can mean reliable travel times and respectable travel speeds, but can also mean equity in terms of offering equal opportunities for all segments of a community to use and enjoy.

As travel patterns changes and demand increases with evolving life-styles or land-use intensification, the transportation infrastructure becomes under-capacity and not able to meet the needs of the community. It used to be a case that this increased demand is met with improved infrastructure capacity involving new or widened roads, but these often proved to be short-lived as demand quickly imposed itself on the increased supply. Hence, many communities and cities have realized the need to improve their public transport system, comprising both buses and subways (often refer to as metros or mass-transit systems).

While useful, the provision of high-capacity public transport systems do not, by itself, relieved the road network of traffic congestion as is evident from many large cities with a decent public transport system. There is a need for a mechanism, other than road congestion itself, to persuade car-users to move to public transport or to travel outside the peak periods. This mechanism is pricing and is often referred to as road pricing but can also be termed congestion-pricing, road-user charging, or similar.

The Economics Theory of Road Pricing

The economics theory to support the case for introducing road pricing is well documented in many literatures, for example, [Arnott \(2005\)](#) and [Wohl and Hendrickson \(1984\)](#). When traffic on a road is very light with no congestion, the average cost faced by each of the few individual motorists can be taken to be that incurred by that motorist alone. Since traffic is very light, there is not much interference or cost imposed from other motorists. When traffic increases, motorists will start to interact with each other and slow each other down. Each additional motorist will cause some slow-down to the traffic stream, imposing this delay to all other motorists already traveling on the road. This is the marginal cost introduced by the additional user, and will increase disproportionately as subsequent additional motorists join the traffic stream, as is indicated by the curve marked MC in [Fig. 1](#). Consequently, the average cost (AC in [Fig. 1](#)) of motorists will also increase as more motorists join the traffic stream. Also in [Fig. 1](#) is the demand curve or sometimes referred to as the marginal benefit curve, signifying the propensity for motorists to join the traffic stream as cost changes. As cost increases with more traffic joining the traffic stream leading to congestion eventually, there will be increasingly fewer motorists willing to join the traffic stream.

Motorists will continue to join the traffic stream as long as the benefit exceeds the cost perceived by that motorist. An equilibrium position is achieved when the benefit of this last motorist who joined in is equal that of the average cost faced by this motorist, and this is indicated as A, corresponding to the flow F_{eq} in [Fig. 1](#). However, at this traffic flow, the marginal cost is much higher because there are delay costs imposed on other motorists by that motorist joining the traffic stream. As a result, there is a social loss to the society and this is represented by the hatched zone. This social loss can be reduced if fewer motorists are using the road, and in fact

Figure 1 Economics of road pricing.

can be eliminated if traffic flow is reduced to F_{op} . A road pricing charge equal to BC can be imposed on motorists to reduce the demand to F_{op} .

To put it in layman perspective, this can be taken to mean that road-users consider only their own cost of travel in deciding whether to travel on that road. They would not consider the (societal) cost imposed on other fellow road-users or to the environment. The additional (societal) cost could be attributed to the little extra delay imposed on all other road-users as a result of that individual joining in the stream of traffic on a road. Likewise, the (societal) cost could be the environmental degradation introduced by that individual and imposed on all present along that travel route, including residents living along that route. Introducing a road pricing charge or toll can eliminate the (societal) cost, which basically means that traffic congestion is reduced or even eliminated.

When there is reduced demand arising from the imposition of the road pricing charge, some of these (marginal) road users will not use the road. They can either travel during another time or use another route with a lower road pricing charge or no charges at all, travel using other means of transport, for example, public transport where this road pricing charge does not apply directly, or even abandoning that trip altogether.

A popular query raised from the introduction of road pricing is on who the beneficiaries are. Obviously, all those who remained on that road and paid the road pricing charge can be viewed as financially worse off, and likewise those that are priced off would be worse off because they no longer enjoy using the road at the desired time, or enjoyed using the preferred transport (i.e., the car) of her choice. However, reduced congestion from the imposition of the road pricing charge meant that all those who remained are actually better off from reduced travel times. The other factor in this scenario is on how the collected road pricing charges would be used. If these are used to improve the road or the public transport option, then obviously there are societal benefits gained.

Early Road Pricing Studies

[Smeed \(1964\)](#) in a report published and named after him more than 50 years ago, provided practical advice for implementing road-pricing schemes. There were nine specified requirements for a workable road pricing scheme, and another eight desirable criteria.

The nine specified requirements listed below are still valid for the several road-pricing schemes that were implemented in the years that followed, after its publication in 1964.

1. Charges should be closely related to the amount of road use.
2. Charges should be variable.
3. Charges should be stable and ascertainable by road users before the start of their journey.
4. Payment in advance should be possible.
5. Incidence of system upon individual road user should be accepted as fair.
6. Method used should be simple for road users to understand.
7. Any equipment used should be highly reliable.
8. System should be reasonably free from fraud and evasion.
9. It should be capable of being applied, if necessary, in the whole country.

The Supplementary Licensing scheme proposed by the then [Greater London Council \(1974\)](#) for the city of London required drivers of certain vehicles to purchase special licenses to use their vehicles at specified times in designated areas. However, the Greater London Council eventually decided not to proceed with the supplementary licensing scheme after it assessed that there would be adverse effects on the lower income motorists and the problems of enforcement. It was also concerned on the possible effect on smaller businesses, industry and travel needs at times when the public transport option was not available, as was reported by [May \(1975\)](#).

Purpose and Types of Road Pricing

The early proposals for road pricing were designed to be essentially manually operated, mainly because the technologies available at that time do not permit more automated road pricing systems. It was only with the advent of electronic tags and wireless communications that electronic road pricing systems became possible.

Nevertheless, the purpose for implementing electronic road pricing needed to be decided upfront to design an appropriate and effective system. While the purpose of road pricing schemes is usually to mitigate traffic congestion, there can be other reasons for introducing it. In recent years, these schemes have a stronger association with environmental protection. Pricing is used to manage the use of higher emission vehicles, whose relatively higher pollutant emissions may be a problem for more sensitive communities, or just for general health reasons. It can also be extended to schemes to meet emission standards arising from climate change protocols. Another purpose for having road pricing may well do with raising revenue to meet various objectives, which may be transport-related, for example, for road maintenance or for improving the public transport system.

Designing a road-pricing scheme is not necessarily a straightforward task. There are many considerations, and it is necessary to have the intent of the road-pricing scheme in mind before the scheme get conceptualized and designed. Depending on the intent of the scheme, one of several types can be used and the basic options as proposed in [Walker and Pickford \(2018\)](#) are as follows:

1. Point-based charging where specified vehicle are charged a fixed amount each time a passing is made.
2. Cordon-based charging, where each entry into a zone defined by the cordon is charged. A variation to this is to also include the payment of a charge even when moving within the cordoned zone.
3. Distance-based charging where the charge is variable and dependent on the distance traveled. This is a refinement of the point-based and cordon-based types because with this, the amount of charge can become more connected and relevant to the actual degree of congestion contributed by each road user.

If the intention is to mitigate congestion, the charging will be applicable only when there is high traffic demand or where congestion would have resulted if there had been no road pricing. Hence, for all three types of road pricing options, there will be defined operating hours and these are usually during the peak morning or peak evening periods, although this can also be throughout the working hours of each weekday. An extension of this concept, in line with the requirements recommended in the Smeed Report, is to have the charges variable depending on the actual traffic demand for road use. Hence, the morning peak period will have a higher charge than during the mid-day period. In fact, [Chin \(2005\)](#) reported that for the Singapore's Electronic Road Pricing (ERP) system, the charges are in 30-min blocks and hence can change every half-hour. However, these variable charges should be made know upfront before the road user gets onto the road, and this is consistent with the requirements in the Smeed Report.

For distance-based charging, not only will the charge be variable depending on the time-of-day but also be dependent on the stretches of road traveled; those stretches with higher traffic demand or congestion will have a higher charge for the same time period.

Regardless of the type of road pricing scheme selected, there are some common issues that have to be considered. One of these is public acceptability, where the majority of stakeholders will have to assess the scheme as being fair, reasonable, and equitable. This means that there has to be a thorough study on who the stakeholders are and the extent to which each group will benefit or suffer. Appropriate complementary measures will then have to be introduced to get a wide enough support for that scheme. These complementary measures include:

1. Improving the public transport system as an alternative for those who are priced off the road.
2. Compensating rebates or reduction in transport-related fixed fees for targeted stakeholders.
3. Appropriate traffic schemes to improve efficiency of existing transport system, so that there is no argument that the road-pricing scheme was introduced because of inefficiencies caused by the failure of the transport agencies to act in the first instance. These include having traffic lights that are well-designed, coordinated, and reliable, having good enforcement action against on-street parking violations as these are often the cause of congestion and effective traffic management schemes.

Communicating the scheme to the many identified stakeholders is an important task, and these can range from town-hall type presentations to small customer-focused discussions to even one-to-one interactions with specific individuals. Hence, it is useful to keep in mind that the scheme should be as simple as possible, so that this is easily communicated, understood and accepted.

Technologies for Road Pricing

The Supplementary Licensing proposal for London in 1974 had (paper-based) licenses pre-purchased for all specified vehicles that intended to enter the priced zone, and it was reportedly not implemented because of (among others) difficulties with enforcement. Admittedly, the technologies at that time were limited and do present challenges for an automated system. However, it did not stopped the introduction of the first area-wide road pricing scheme in 1975, in the Central Business District (CBD) of Singapore.

Called the Area Licensing Scheme (ALS), [Chin \(2002\)](#) reported that the technologies used for this manually operated road-pricing scheme were not sophisticated. Many of its processes were manual. It relied on the pre-purchase of paper licenses from convenience stores, post-offices, and sale booths just outside the CBD. The CBD cordon was marked out with physical gantries, and carried the words "Restricted Zone" accompanied with a set of amber lights. These sets of traffic lights were switched on manually by the enforcement officers based on the time of their watches. Some flexibility was allowed for the switching on of the amber lights, as

it was not wise to do so when traffic was flowing through it because the traffic lights were showing green. Hence, these were switched on only after the traffic lights had turned red to stop the traffic entering the CBD. Enforcement was undertaken by enforcement officers stationed at each of the gantries, who would note down the registration numbers of vehicles that were seen without the pre-purchased license valid for that day.

Even though the ALS was a manually operated scheme, the processes can be grouped under three functional categories, that is, the unique identification of vehicles, the payment mechanism and ensuring compliance. These three functional categories are also relevant for electronic road pricing, and the possible technologies that could be adopted for each of these categories are described in the next sections.

Unique Identification of Vehicles

For road pricing to impose a charge on vehicles passing through a pricing point, it must be uniquely identified so that there is a proper record of there being a valid charge imposed for that particular vehicle. Traditionally, vehicles on the roads are identified by their vehicle registration number plate. For electronic road pricing, each vehicle has also to be identified uniquely in an automated manner. The identifier can be the vehicle's registration number on its vehicle plate, and these can be read by LPNR (license plate number recognition) techniques. This is the method used by the road pricing system in London and Stockholm to identify each vehicle uniquely. Alternatively, each vehicle can be fitted with an on-board electronic tag that carries a unique electronic code, and this can be read by roadside readers or antennae via radio frequency or other wireless communications. This is the system adopted by the Electronic Road Pricing (ERP) system in Singapore. A requirement is that the on-board electronic tag must be permanently linked to that vehicle (which is often the registration number of the vehicle's number plate). Checks can be randomly made to ensure that this remains so, from matching the electronic code from an installed on-board tag to that of the vehicle's license plate.

There have been some proposals to use a driver's mobile phone as the vehicle identifier for road pricing, but this is fraught with problems. Drivers can forget to bring their mobile phones when they get into their vehicle, or may have brought another mobile phone instead. There is also the possibility that the battery power can run out during a particular trip, and becomes inoperable. While the mobile phone is used as an identifier, there will be a need for an apps to be running to do all the functions required of road pricing, and the issue will be whether the driver will activate the apps before starting their journeys or in a worst case scenario, make illegal and unauthorized modifications to the apps to allow, for example, travel with no charges deducted.

Payment Mechanism of the Road Pricing Scheme

The second category of a road pricing function focuses on the acceptance and recognition of payments made by the road user. Payments can be made in advance, at the time of using or even after having used the priced roads. The important aspect of these payments is that it must be accurately associated with the vehicle for which this payment was made, that is, it should be linked to the identifier used for that vehicle.

For payments made in advance, the amount is linked to the identifier and kept in a backend database. Also recorded in that database is often the date or time for which the payment is valid for. Hence, when that vehicle identifier, for example, the vehicle registration number read off a LPNR system is picked up later, it is used to search against the payment records in the database. When the unique identifier is found, it is then taken that the payment has been made for that day or time period. This is the system used for the London's congestion pricing.

Payments can also be made at the point of using the priced road. This requires the system to uniquely identify the vehicle and made the deduction of the road pricing charge from a stored value account. The stored value could be on a smart card inserted into a reader or electronic tag, like that used in Singapore's ERP system or it could be in a backend account held with a financial entity or a bank. With the latter, this requires the transmission, usually wirelessly, of the unique identifier of the vehicle that used the priced road to this financial entity or bank. Together with other information like the time of day and location of the priced road, the correct amount of road pricing charge is deducted from that stored-value account.

It is also possible that the payment is made after the use of the priced road, and this is often useful when the road user decides to use the priced road at moment's notice for whatever reason. The payment system can be designed to accept payment for some time, usually by the end of that day or even the following day after the road user has used the priced road.

Ensuring Compliance

Road pricing schemes are often not popular with motorists and hence, there will always be the tendency of motorists to find shortcomings in the system to avoid paying the charge. Hence, this third functional category of ensuring compliance is just as important.

Ensuring compliance need not mean just an effective enforcement system, with detection devices like video cameras to capture non-payments or road users interfering with the normal operations. Publicity on the need for road pricing to benefit the community as a whole could also serve as a means for motorists to understand the rationale for paying the road pricing charges and willingly pay the charges when needed to. The publicity can also be on the high reliability of the detection devices to capture all non-payments, to the extent that road users will just pay since there would be no way to avoid not being detected.

Of course, the detection devices and the processes to capture non-payments must be highly reliable. Often the unique vehicle registration number on its license plate is the identifier used to determine the vehicle owner. The vehicle registration number captured by high-resolution video cameras would then be processed with optical character recognition (OCR) techniques at the

backend to automatically read and identify the vehicle registration number. There will always be a small number that could not be read by the OCR techniques and when this happens, it is often that the video image is then viewed manually by a human operator.

The legislation will often have the owner of the offending vehicle also the person liable to pay any penalty. However, it is conceivable that the driver of a vehicle is not the owner of that vehicle as in the case of fleet vehicles or rental vehicles. Hence, there must be a process to deal with this sort of situation. This could simply have the owner of an offending vehicle be provided with a channel to report on who the driver was at the time when the offence took place, and allow the penalty to be imposed on the named driver instead.

Examples of Implemented Road Pricing Schemes

Singapore

In 1998, Singapore had its manually operated ALS replaced by an Electronic Road Pricing (ERP) System. It used Dedicated Short-Range Communications technology for reading information from uniquely coded In-vehicle Units (IUs) that are fitted to vehicles that opted to do so. The fitting of the IU is not mandatory although almost all vehicles do so, because the same IU can be used for entry and exit into car parks. However, it is mandatory for an IU to be fitted when the vehicle passes through a pricing gantry during its operational hours.

The IUs, with its unique identification code, are used by the ERP system to recognize payments associated with it. This unique IU code does not carry the identity of the vehicle nor particulars of the vehicle's owner. This is in line with safeguarding the privacy needs of motorists and the link to vehicle's owner is only established for enforcement actions.

The IUs accept a national stored-value card issued by the local banks, and this is inserted into the IU to effect payments—for passage through road pricing gantries and also for payment on exit of car-parks. This stored-value card can be taken out from the IU to facilitate topping up of its value at banks' ATMs or at convenience stores. In recent years, the ERP system has also been modified to allow ERP payments to be deducted from back-end accounts of vehicle owners. After signing up for this mode of payment, there is no longer the need to insert the stored-value card into the IU. Instead it recognizes registered IU codes, and effects the back-end payments instead of taking it as a non-payment case.

To ensure compliance, all the road-pricing gantries are fitted with infrared enabled cameras to read license plate numbers of non-complying vehicles, that is, those that do not pay the road pricing charge. The OCR technique to automatically read the license plate numbers is not able to read all of them for a number of reasons (e.g., dirty license plates) and if so, the pictures taken by the cameras are used for manual processing. Vehicle owners are identified and issued with letters to make good the non-payment but with the addition of an administrative fee. However, if the vehicle owner does not make this payment asked for in the letters issued to them, they will be issued a traffic summons for which the non-payment can result in them being subsequently issued a court summons.

The ERP system started operations in 1998 with 33 road pricing gantries, with most of these forming a cordon around The Central Business District (CBD). Since then, more road pricing gantries were introduced at specific locations on the expressway network, and also about an outer cordon bordering the Outer Ring Road system of the CBD although this outer cordon is "leaky" in that there are several roads on the western part that are not priced. Hence, there are a total of 78 road-pricing gantries today (2019).

The road pricing charges vary throughout the day, with them changing as often as every half-hour. For the CBD, motorists are priced throughout the day from 8 a.m. to 8 p.m., with the exception of a 2-hour break from 10 a.m. to 12 noon. Elsewhere, the road pricing charges are mostly during the morning and/or evening peak periods.

The reason for varying road-pricing charges is because the intent is to keep operating speeds for each half-hour period within an optimal range based on speed-flow studies. For expressways, the optimal range is between 45 to 65 km/h. For other roads, this is between 20 to 30 km/h. The speeds for each half-hour are measured every 3 months to determine if the road pricing charges should be either increased or decreased. After years of operations, the road pricing charges do not vary often and have kept relatively stable.

While the ERP System has worked well for Singapore over the past 20 years, there are plans to replace this with a Global Navigation Satellite System (GNSS) based system where there is no need for physical road pricing gantries. Each on-board unit (OBU) in the vehicle uses satellite signals to determine its location, and based on this decides if a road pricing charge is to be imposed. Payment is expected to be either through a stored-value card or a backend account, similar to the practice used for the current ERP system. Enforcement is still necessary through cameras installed at strategic locations in the road network.

London

London's Congestion Pricing Scheme was implemented in 2003, and requires specified vehicles entering or remaining in Central London or the Charging Zone between 7 a.m. and 6 p.m. on weekdays, to pay the congestion charge. Details of this scheme are available in [Transport for London \(2007\)](#)'s report. The scheme was extended to the west of the city to an area that is known as the Western Extension Zone in 2007. This was, however, scrapped at the end of 2010.

The unique identification of vehicles is based on their license plate number, and this is read with cameras installed at entrances into Central London, as well as within Central London. The Congestion Charge is a fixed daily amount and this payment can be made in advance or on the day of use up to midnight that day. The user would provide the vehicle's license plate number together with the payment. There is also a provision for payments on the following working day, although this would attract a higher charge. All these payment information is stored in a backend database.

Following the detection and reading of vehicles' license plate number within the Charging Zone, this is compared to the list of vehicles that have paid in the backend database. If there is a match, the detected vehicle is taken to have paid the Congestion Charge. If there is no match, it will be taken that there has been a violation and a Penalty Charge Notice (PCN) is issued.

There are discounts and exemptions for specific vehicles in the Congestion Charging scheme. For example, residents are offered a discount of 90% while emergency vehicles and taxis are exempted from the payment. Private hire vehicles, which had enjoyed the exemption in the past, are no longer exempt and they pay the prevailing Congestion Charge like any other similar vehicle.

There is also a parallel Ultra Low Emission Zone (ULEZ) that operates for the same Congestion Charge zone, and vehicles that do not meet the minimum emission standards will have to pay a fee to enter and remain within the zone. Although this is strictly not a road-pricing scheme, it has the effect of managing the traffic within Central London.

Stockholm

Stockholm's charging scheme started in January 2006 as a pilot for 7 months and requires specified vehicles to pay a charge for entering or leaving the inner city from 6:30 a.m. to 6:30 p.m. on weekdays. Eliasson (2014) describes the scheme and its traffic impact, with the varying charge dependent on the time of day, with the maximum during the peak morning and evening periods. The pilot ended at the end of July 2006 with a referendum that had its residents voted in favor of the charging scheme, mostly because of the improvement in traffic congestion during the pilot. It started operations again in August 2007.

Like the London's Congestion Charging Scheme, the unique vehicle identifier for Stockholm's is the vehicle license number plate. It uses cameras to capture the vehicle's license number plate and imposed the relevant charge (based on the time-of-day) on that vehicle. Since the charge is time-dependent, it was not possible for payment in advance. Instead, an electronic invoice for all applicable charges for each month is sent to the vehicle owners. Payment can also be by direct debit from their bank accounts.

Since this is a post-paid scheme, there are technically no violations on the ground. The violation, if it occurs, comes from non-payment on receiving the electronic invoice.

Conclusion

Since the introduction of road pricing in Singapore, London, and Stockholm, there have been several other cities that have followed suit. These include Milan and Gothenburg, although the purpose for doing so in these cities have not been entirely to deal with traffic congestion.

While there are cities that introduced road-pricing schemes, there are also others that have attempted to do but did not get the support to do so. These include Manchester, United Kingdom where the referendum in 2008 had its residents not in favor of it and in New York City in 2007 where the NY State Assembly blocked it. Interestingly, New York City has now (2019) started to develop its road-pricing scheme again with the aim of not just relieving traffic congestion, but also to raise revenue to improve its public transport including its subway system.

Ultimately, the introduction of road pricing schemes is a complex one. It is often just one element in any communities' transport strategy, with the alternative of an effective and affordable public transport being an important complementary one.

Introduction

This is the first of four articles that introduce the role of pricing in the establishment of an efficient transportation system for cities. In this article we develop the key theory of marginal cost pricing, subsequent articles use this: to develop the equilibrium conditions for highways in the short and long run; the complementary role of pricing public transportation; and finally, a case study of the application of electronic road pricing to Hong Kong.

Congestion pricing, popularly known as road pricing, aims to reduce excessive traffic during rush hours to the Central Business District (CBD).¹ Since the social cost of a trip typically diverges from its private cost, a congestion charge is imposed by an economic efficiency-enhancing authority to internalize the external effect brought about by a motorist. By doing so, total travel times by motor cars and buses to and from the CBD, together with their vehicle operating costs, are saved. In a wider context, road pricing is the application of market-oriented principles to curtail excessive automobile traffic and to encourage the use of public transportation. Our framework is to adopt the principle of marginal cost pricing on both private transportation via a congestion toll and to public transportation via an optimal transit subsidy. Without pricing as a quasi-market mechanism's signal, public transportation services by municipalities are likely to continue to suffer mounting deficits. Road pricing would constitute an indispensable part of a sustainable transport package of road and public transport provision.

An Analytical Framework for Charging Excessive Use of Private Transportation

Traffic congestion is well studied in the traffic engineering and the transportation economics literature (Dupuit (1844, 1849), Greenshields, 1935, Wardrop, 1952, Beckmann et al., (1956, Article 3), Vickrey (1955, 1969), Walters (1954, 1968)). We start with the technology of road congestion by assuming that homogeneous vehicles move uniformly on a stretch of urban road (Mohring and Harwitz (1962, Article 2)). By following a defensive driving rule and avoiding tailgating, a driver is advised to maintain a comfortable distance by counting 3 s behind the car in front of him. This so-called "three-second rule" roughly translates to the conventional safety education dictum of maintaining one car length for every 10 miles per hour (or 16 km/h) that one is cruising along. If all motorists adhere to such safe driving practice, a linear relationship between traffic density, D , in vehicles per kilometer per lane, and traffic speed, S , in kilometers per hour, follows:

$$F \equiv \text{Speed} \cdot \text{Density}$$

$$F \equiv S \cdot D$$

vehicles per hour per lane $\equiv$ kilometers per hour $\times$ vehicles per kilometer per lane

The identity says that traffic flow is the speed at which vehicles move times the number of vehicles in a lane-kilometer (Fig. 1A). Institutionally, a speed limit, $S^{\max}$, is often imposed by society on motor vehicles in order to lower traffic speed from the technologically achievable, S^f , as shown by the horizontal stretch leading up to the kink in Fig. 1A,B. At first, with a few entrants on the road, increased interactions amongst the vehicles would yield an increase in traffic flow but at a diminishing rate. At the largest traffic flow – as shown by a rectangular area in Fig. 1A – civil engineers' "optimal" density, D^m , and "optimal" speed, S^m , are reached. This point, at which normal congestion turns into hypercongestion, is the maximum capacity (or engineering capacity) at $F^{\max}$ (see Fig. 1B):

$$F^{\max} \equiv D^m \cdot S^m$$

However, with many more vehicles per hour entering the roadway, traffic speed continues to fall. Past a certain point—the mid-point of the linear speed-density relationship—traffic flow begins to fall rapidly until traffic flow and speed becomes zilch (see Fig. 1B). Instead of deriving the famous bullet-shaped speed-flow curve in this way, we could tell the story slightly differently: as more

¹ Here we deal mainly with congestion pricing as opposed to marginal social cost pricing, which is defined to include both the private costs and the external costs of congestion, air pollution, noise pollution, accidents, road damages and climate change (see Hau (2005a), Small and Kazimi (1995) for example).

Figure 1 Fundamental Diagram of Road Traffic: Expressed in three forms based on the identity flow = $F = S \cdot D$

and more vehicles per distance of road space increases, traffic volume increases at first but falls until traffic comes to a standstill and jam density, D^{jam} , is reached, with the road becoming a parking lot (see Fig. 1C). The density-flow curve, or the flow-density curve with the axes reversed, in Fig. 1C, is “the fundamental diagram of road traffic” coined by Frank Haight (1963, article 3).² The initial downward-sloping part of the speed-density diagram is referred to as the congested or normally congested part (shown as the bolded portion of the line) whereas its latter part is called the hypercongested part (shown as the unbolded portion) (Fig. 1A).³ (The figure for

² As the fundamental relationship of such a steady-state traffic flow of identically-operated vehicles traversing a road uninterruptedly is an identity, the congestion technology could be expressed equivalently as a functional relationship between any two of the three variables: F , S and D (see Small and Verhoef, 2007, Chapter 3). As an illustration, consider the flow-speed relation: the third variable, density, D , is simply the slope connecting the origin to any point on the flow-speed relation. Similarly, for the flow-density relation, the third variable, speed, S , is the slope connecting the origin to a point on the flow-density relation.

³ Similarly, the normally congested part appears in a different form on the upper branch of the speed-flow curve (shown as the bolded portion of the curve) whereas the hypercongested part appears on its lower branch (shown as the unbolded portion) (Fig. 1b). Finally, the normally congested part once again appears on the lower branch of the density-flow curve (shown as the bolded portion of the curve) whereas the hypercongested part appears on the upper branch (shown as the unbolded portion) (Fig. 1c). The properties of such an identity have just been described. The last figure on the southwest quadrant is merely a 45 degree line that connects the values of density, thereby relating the speed-density diagram with the density-flow diagram: it is a mirror image of itself.

the engineering capacity for a typical expressway is about 1800 – 2000 vehicles per hour per lane at 50–55 km/h (or 30–35 miles/h) (see Gerlough and Huber (1975, article 4), Transportation Research Board (2011), Wong and Wong (2016) and any Highway Capacity Manual, for example, Transportation Research Board (2016)).

Drawing a parallel of our four-quadrant diagram with that of the principles of microeconomics is useful. With a conventional downward-sloping linear demand curve where price is placed on the vertical axis and quantity demanded is plotted on the horizontal axis in the northwest quadrant as in Fig. 1A, total expenditure comes about from the product of price and quantity, resulting in a price-total expenditure curve in the northeast quadrant as in Fig. 1B and a quantity-total expenditure curve in the southeast quadrant as in Fig. 1C. At the peak of the total expenditure–price curve and that of the total expenditure–quantity curve, the price elasticity of demand is unity. Pricing a good or service at a medium level, synonymous with the quantity demanded at a medium level for a linear demand curve, naturally yields the consumer's largest total consumption expenditure. Any price or quantity demanded that deviates from this middling level will result in a diminution of total expenditure and a price elasticity of demand that departs from unity.

Given a trip distance of 1 km of road stretch, say, the civil engineer's speed–flow curve (Fig. 1B), reproduced as Fig. 2A, is straightforwardly inverted to become an (average) travel time–flow curve, as travel time is the reciprocal of speed (Mohring, 1999). Travel time enters as the primary input into the production of a vehicle trip and, together with the money cost of travel, constitutes the costs of a trip. Travelers are frequently observed to trade off travel time with money so an estimate of the (marginal) value of time could be obtained from modal choice models' calibration of the shadow price on travel time.⁴ By using a representative value of time estimate, one could straightforwardly convert travel time (in time units) into time cost (in dollar units).

Money outlay is assumed to be independent of output. At low traffic density, motorists could drive fast, incurring high fuel costs. At high traffic density, vehicles slow down thereby lowering fuel costs, but with motorists having to weave in and out of heavy traffic and slow down, high fuel costs are incurred too. These two factors roughly cancel one another out, leading to the rough approximation that the costs of operating an automobile—which include fuel, engine oil, maintenance, and depreciation costs—are roughly independent of the level of traffic flow (Mohring (1976, article 3), AASHO's (1960) "Red Book"). The money cost, known as the vehicle operating cost, could therefore be summed up on a par with time cost, forming the traveler's generalized cost, GC (see Hau, 2005a). Writ small, the Average Travel Time curve, ATT, in Fig. 2B could then be thought of as a typical traveler's travel time of a trip depending on the traffic flow, ATT(F), and, after being rescaled by the value of time measure, becomes the traveler's average travel time cost, that is, the Average Variable Cost of a trip, AVC(q), in Fig. 3.⁵ Since the money cost component merely shifts the AVC curve up in a parallel manner to form the generalized cost of a trip, GC, henceforth we shall set the money cost aside to avoid cluttering our diagrams.⁶ So it is the time cost element alone that drives the AVC curve. The AVC curve climbs upwards due to significant adverse interactions amongst vehicles well before the traffic flow reaches the maximum capacity, $F^{\max}$, relabeled as maximal output $q^{\max}$, in Fig. 3.⁷ The shape of the AVC curve, being driven solely by the ATT curve, comes about from an inverted speed–flow curve. Hence in actuality the AVC curve is a technology or performance curve generated by all travelers rather than a single one. The concept of "transport supply" is nonexistent in such a setting: generalized cost depends on output, GC(q), and not the other way around. Causality only holds in one direction, as distinct from a conventional supply curve in economics.

When travelers formulate their decisions on the amount of travel to undertake, as consumers they are really basing their decisions on a combination of their travel time and travel costs, or the generalized price of a trip, commonly referred to as the full price of a trip, P (Mohring (1993), Mohring (1994, Introduction)). Obeying the law of demand, aggregate travel demand is responsive to the (full) price of a trip in a standard manner, $q^D(P)$. That is, when the full price of a trip is high, travel demand is low and vice versa, as reflected by a downward-sloping demand curve as depicted in Fig. 3. The demand curve is a typical traveler consumer's travel demand for the amount of trip taking depending on the full price of a trip..

Optimal Pricing

Whether or not a traveler makes a trip is contingent on the following calculus: the marginal benefit of undertaking a trip with the cost of undertaking that incremental trip to him, which is simply the amount of travel time that he incurs *on average*, that is, the average variable cost of the trip (and *not* its marginal cost). The marginal benefit of a trip is his marginal willingness to pay for an incremental trip as reflected by the inverse demand function of $P(q)$. With the traveler basing his decision to travel on the AVC curve, and with the functional relations of GC(q) and $P(q)$, the traffic equilibrium point—depicted as point U in Fig. 3—is characterized by $P(q) = GC(q)$, with q^0 and P^0 as its solution. Since GC is simply a translation of AVC, the interpretation of one is synonymous with the other. In equilibrium, we say that $P(q) = AVC(q) (=SRAVC(q))$ for simplicity.⁸ Point U is an equilibrium because there is a built-in tendency

⁴ There is a voluminous literature on estimating the values of travel time using disaggregate behavioral travel demand models in the transport literature (Beesley (1965), McFadden (1974, 1978), Train (1980), Hau (1987), Hensher (2001)).

⁵ Thus $t^{\min}$ is the minimum travel time of a trip (see Fig. 2b). When multiplied by the value of time, the fastest travel time of a trip, $t^{\min}$, gets converted into money terms and appears as t^M (see Fig. 3). Hence the ATT and AVC curves have identical shape.

⁶ Note that the magnitude of the money cost clearly does matter but it is not germane to our analysis.

⁷ When switching to the standard output notation that economists use, the traffic flow per hour unit could be expressed as a commensurate per unit of time measure for user benefit and cost of road capacity later on.

⁸ To avoid notational clutter, the italicized P symbolizing the inverse demand function shall be replaced by the regular P symbol, with the inverse demand function interpretation clear within the context. Note that the money cost appears on both the willingness to pay side and the time cost side, canceling one another out in our framework.

Figure 2 (A) A speed-flow curve; (B) Average travel time curve and marginal travel time curve.

for traffic to converge to that point.⁹ Thus far we have confined ourselves to considering a motorist's private costs. In the absence of congestion, private and social costs are the same. However, the social cost of one's private actions may diverge from one's private cost, due to an external effect that is left unaccounted for by the motorist.

The incremental cost to society of a motorist is that his entrance onto a road pushes up the average variable cost of a vehicle trip to everybody else. This is because the traveler is concerned only about the prevailing traffic condition as it affects himself. While he clearly accounts for the time that his own vehicle trip takes on average, the motorist is not mindful of the fact that he causes a definite delay, whilst a bit small, to each of the vehicle trips behind him when he joins a traffic stream, ending up as a nontrivial amount in

⁹ That points U and X are both stable equilibria and point W is an unstable equilibrium could be shown by perturbing the respective equilibrium using an output level slightly greater or lesser than the points U, X and W (see Hau (2005a)).

Figure 3 Welfare impact of road pricing.

the aggregate. In order to ensure that the motorist is responsible for his own behavior, the public-spirited road authority places an economic efficiency-enhancing toll on the *excess* of the marginal cost over the average variable cost at the traffic level where the travel demand meets the marginal cost curve.¹⁰ The congestion toll, shown as the distance YT in Fig. 3, is imposed to ensure equality of the

¹⁰The incremental cost or marginal cost of undertaking a vehicle trip, $MC(q)$, is: $MC(q) \equiv \frac{\Delta C(q)}{\Delta q} = \frac{\Delta TVC(q)}{\Delta q} = AVC(q) + q \cdot \frac{\Delta AVC(q)}{\Delta q} = AVC(q) \cdot (1 + \epsilon(q))$ where $\epsilon(q) \equiv \frac{\frac{\Delta AVC(q)}{\Delta q}}{\frac{AVC(q)}{q}} = \frac{\Delta AVC(q)}{\Delta q} \cdot \frac{q}{AVC(q)}$. $MC(q)$ is the Marginal Cost function, $C(q)$ is the cost function, $TVC(q)$ is the Total Variable Cost function, $AVC(q)$ is the Average Variable Cost function, is the output elasticity of the AVC function. Intuitively, marginal cost is the sum of two components: the first one is the traveler's Average Variable Cost, $AVC(q)$, and the second one is: $q \cdot \Delta AVC(q)/\Delta q$. The first term consists of the trip maker's own time cost, time in money terms converted from travel time via the valuation of travel time measure; the motorist himself incurs the time cost so we say that it is self-financed. The second term is the marginal external cost; it is the rate of change of the trip time cost to others due to his last vehicle entering the traffic stream, $\Delta AVC/\Delta q$, multiplied by the ensuing platoon of vehicles, q , that his incremental vehicle has slowed down. By multiplying and dividing the second term by AVC , the marginal external cost could be expressed as the product of the Average Variable Cost, AVC , and the output elasticity, ϵ . Because only the average variable cost, AVC , is accounted for by the trip maker himself, the external cost engendered by him – the second term – needs to be internalized by having a congestion toll required of him by the road authority. The public sector's call to pursue marginal cost pricing of a trip means that (full) price is set equal to marginal cost but with his time cost already self-financed, internalizing the externality calls for a congestion toll to be set at the *difference* of marginal cost and average variable cost. (It is on a per-unit-of-time basis just like traffic flow is.) Charging anything more than the external effect would be double-counting. Setting the two marginals equal would mean that the user benefits of highway-derived travel are maximized, given a road system. The congestion toll is also known as an optimal, economically efficient, efficiency-enhancing, net-benefit maximizing, Pareto Optimal, marginal cost or efficiency toll in the economics and transportation literature. To be valid, the toll wedge shifts the upward-sloping part of the AVC curve, i.e., the normally congested part of the AVC curve for the section from t^M leading up to point V only. Corresponding to the AVC curve, the MC curve rises asymptotically up to the capacity level of $q^{\max}$. Note that with a congestion toll, the capacity $q^{\max}$ would not be reached in equilibrium. It would be convenient to redefine the capacity $q^{\max}$ as K as different models of speed-flow relationships may not yield a backward-bending Average Travel Times curve with a capacity emerging just at the switching point from normal congestion to hypercongestion, so we can write: $AVC(q, K)$. The traffic flow on a per hour basis could then be expressed as being commensurate with a per-unit-of-time measure for the cost of road capacity and user benefit to be introduced later on. First-best pricing in the world of transport implicitly presumes that the rest of the economy is efficiently priced also.

marginal benefit of a trip and its marginal cost.¹¹ Such a toll wedge, τ' , shifts the upward-sloping AVC curve by the toll magnitude upwards in a parallel manner, resulting in a new equilibrium at point Y: $P(q) = MC(q) = AVC(q) + \tau'$. Price is driven up to P' and quantity demanded falls to q' . With the equimarginal principle satisfied, the net benefits of road use travel are maximized and indicated by the large triangular area $a + b + e + h$. Point Y is known as the Social Optimum (SO). This is called the first-best Optimal Pricing Rule, our First Optimality Rule. Once congestion pricing is introduced, not only would the final traffic level equilibrate below the initial equilibrium, q^0 , it would be at a level well below the capacity of the road, $q^{\max}$, the point at which hypercongestion sets in. The grossly inefficient backward-bending, hypercongested part of the average travel time curve in Fig. 2B and its AVC counterpart in Fig. 3 would be obviated completely under congestion pricing.

As an illustration, suppose a 10-mile trip from one place to another that takes half an hour during uncongested hours, denoted by $t^{\min}$ in Fig. 2B, and 45 min during rush hour at height Uq^0 . The motorist is fully cognizant that it would take him 45 min—a cost of which is *internal* to the driver—when traveling during the peak period but is oblivious to the fact that, consequential to his entry, he would be imposing an additional 20 min, say, of travel time, at height ZU, the *external* cost to the drivers behind him. Alternatively, if that last trip is eliminated altogether, the marginal motorist diverts his resources to other uses, including his 45 min of travel time, whilst *every* motorist staying on the road reaps a saving of travel time as a result of experiencing slightly lower traffic delay. It is the 20 min—of a trip that costs a whopping 65 min in total (at height Zq^0)—for society that is the congestion externality to be charged for in the form of a congestion charge were it to be evaluated at the initial traffic equilibrium, q^0 . Since travel demand responds to the (generalized) price at that high level, the number of vehicles on the road would be curtailed and congestion drastically reduced. The road authority should then respond accordingly and adjust the toll to a lower level in anticipation of the ensuing low traffic level and the corresponding smaller difference of marginal cost over average variable cost. After various trial-and-error iterations, the number of trips demanded could be viewed as moving in a cobweb manner, eventually converging to where demand intersects the marginal cost curve (at q'), and calling for an optimal toll-wedge: $YT = \tau'$, evaluated at the final equilibrium point q' , given the existing road capacity.¹² Note that the optimal toll, in the final analysis, would be at an intermediate level since the optimal level of congestion externality—akin to the notion of an optimal pollution level—should neither be zero nor an inordinate amount under normal travel demand conditions. In terms of either time unit or time cost, the marginal travel time delay at the final equilibrium traffic level (at q') would be less than 20 min since certain trips would be priced off the road, given a conventional travel demand that is downward sloping.¹³ In particular, the toll should be set equal to the marginal delay (of a fraction of a second, say) caused by an additional vehicle entering the roadway at the final equilibrium level multiplied by all the ensuing vehicles (at, say, 1000 vehicles per hour per lane). This results in a marginal delay of 10 min to others.¹⁴ Assuming that the value of time is HK\$60 an hour, or a dollar a minute, in our example, the numerical value of the congestion toll comes to HK\$6.¹⁵

The Welfare Impact of Congestion Pricing

Here we seek to explain the political failure of road pricing using the standard analytical tools of welfare economics. An economist might pose the question at hand as follows: why is it that the imposition of an externality-corrective tax in road transport, which we know yields a welfare gain overall to society, would end up hurting *all users*—not unlike the case of a distortionary excise tax would on the users and producers of a commodity.¹⁶ Putting it more mundanely, why would the imposition of a congestion toll fail to be accepted by the majority of people if the welfare gain is demonstrably positive?

For simplicity let us consider what happens when a congestion toll is imposed on road users in a moderately congestion situation without a preexisting toll or tax. The resulting increase in price means that certain motorists are tolled off the road. These motorists will value the reduction in those trips as the sum of the valuation, that is, the marginal willingness-to-pay, for trips between q^0 and q' , as indicated by the trapezoidal area YUq^0q' (area $d + g + k$). On the other hand, the released resources constitute the sum of the marginal costs of trips to society between q^0 and q' as shown by the larger trapezoidal area YZq^0q' (area $l + d + g + k$). At first glance, it appears that the incremental resource savings over and above the incremental benefits accrue to those users that are priced off the road when it turns out that the ones who benefit belong to those who had stayed on and paid the congestion toll. Another way of representing the change in variable costs of the q^0q' trips is shown by the inverted L-shaped area $P^0RUq^0q'TA$ (area $e + f + g + k$). The equivalence of these two simple approaches has an important economic interpretation: the savings in time costs to society from not undertaking ($q^0 - q'$) trips are broken down into two parts, with the first part, area RUq^0q' , being the (private) savings in resources accruing to those tolled off, and the second part, area RYZU, being the formerly savings in external travel time cost accruing instead to all those motorists who remain on the road: the tolled. The *bona fide* benefits from congestion pricing can be shown to be the familiar

¹¹ Note that the optimal toll is expressed on a per-unit-of-time basis so that it is commensurate with the time cost and traffic flow variables.

¹² Li (2002) uses the Drake model of speed-flow relationship to come up with the congestion toll and a value of the generalized cost even without having to specify a demand function.

¹³ p^0 is the money equivalent of 45 minutes, converted into money via the value of time, at the initial traffic level, and P' and A correspond to the travel time cost of 51 minutes and 41 minutes respectively. Note that the numerical example with round numbers are given for illustrative purpose only.

¹⁴ The numerical example implicitly assumes that the nonlinear average variable cost curve is assumed locally to be linear, with the linear demand drawn as being more unresponsive to price relative to the (technological) performance curve.

¹⁵ The official exchange rate is HK\$7.80 to US\$1.

¹⁶ Note that the results put forth here from congestion pricing do not carry over to the case of a corrective tax for pollution externality, say. This is because the curtailment of the excess amount of pollution results in savings in social cost by the group of incremental users over and above the valuation by the same group of marginal users. By contrast, with congestion pricing, the savings in external time costs released by the marginal users accrue technologically to the inframarginal users and *not* to the marginal users. It is in a sense such as this that some may find the concept of congestion pricing a bit elusive.

triangular welfare gain, area YZU (area l) or, equivalently, the rectangular area of the actual time savings accruing to the tolled, area P^0RTA (area $e + f$), less the welfare loss area YUR (area d), to those who are tolled off. As a result of curtailing the excess number of trips, q^0 less q^* , in this way, congestion is eased and travel time drops. The *incidental* time actually saved of one trip to those who remain on the road is shown by the distance RT in Fig. 3 and the aggregate time savings are valued at P^0RTA (area $e + f$), equal to \$400 in our example, while the aggregate toll payments are given by the area P^0YTA (area $b + c + e + f$), \$1000. Note that the time savings in a normally congested situation is *always* less than the toll payment (of distance YT), so that the tolled (i.e., those who chose to stay and pay) are worse off in the presence of congestion pricing than without, under the standard assumption of a uniform value of time (adopted universally by authors such as Walters, 1961, 1987, Vickrey, 1969). Were this not the case, that is, if people value their time savings greater than their toll payments, people would not be willing to switch mode or time of travel—and no decongestion would emerge! Those who are tolled off¹⁷ (i.e., those who avoided using the road to shun the toll) are clearly worse off also because they would be obliged to take a less preferred route or desired mode or time of travel, with the so-called deadweight loss shown by the triangular area YUR (area d) (see Hau (2005a, Appendix) for other derivations). Furthermore, those who are currently traveling during off-peak or on public transportation may find themselves being overcrowded—a group I call the “tolled on”—so that they too are made no better off than before. (Those on buses *could* experience a net gain in welfare if: (1) equilibrium travel times—in addition to line-haul travel times—along the transport corridor were sufficiently lowered as a result, or (2) if increased patronage were to come about due to increased frequency or service enhancement by the transit agency.) If all these groups are made no better off, who gains unambiguously most of the time? The answer is that the road authority—and *not* users—is the only party that gains unequivocally in the form of reaping the toll revenue collection (area YT q^*), which is \$1000 in our example). However, the government’s gain comes about actually because motorists who have opted to continue to travel during the peak period are required to surrender a toll payment for the right of access: total congestion toll revenue equals total expenditure. In economic jargon, the toll revenue collection is a pure “transfer payment”. The welfare gain of road pricing remains as before: the aggregate time savings of the tolled less the welfare loss to those who are tolled off. This is the genuine benefits of road pricing.

Note that implicit in this whole exercise is the common practice of adopting what at first appears to be a fairly innocuous assumption in road pricing: that the congestion toll revenues are redistributed in a “lump sum nondistortionary” fashion entirely back to the people, which in this case turns out to be the tolled.¹⁸ But adopting this seemingly innocuous assumption for public policy analysis runs counter to the general contention that the public regards road pricing as “just another tax” (as in several ill-fated Hong Kong electronic road pricing trials and other failed road pricing experiments elsewhere), as opposed to being properly regarded as a *price* for road use. Only by explicitly introducing road pricing as a *road use fee* and recycling the proceeds towards users’ direction would the tolled be made better off by the aggregate time savings area ($e + f$). If not, both the tolled and the tolled off are in fact worse off—as reflected in a diminution of their consumer’s surplus of area ($b + c + d$)—as a combined group. One should therefore not be surprised to find road users decrying so-called “congestion” pricing since their hunch is correct: that this governmental innovation is an instrument that adds insult—the tax—to their injury—being stuck in traffic. Actually, motorists generally realize that they are “not getting their money’s worth”, so to speak, especially if the congestion toll revenue collection is siphoned off to a more appealing or a higher purpose of partially paying off the interest on the national debt, say. Motorists are unlikely to perceive that the reduction in congestion is due to their behaving in an economically efficient manner when faced with the correct signaling from a road use price.

Distribution of the Values of Time

For policy analysis, we now ask whether or not the results obtained thus far based on the assumption of a constant value of time carry over when replaced by a distribution of values of time assumption. The strong conclusion reached above that in a moderately congested situation *all users* would be made worse off with the exception of the government entity needs modification:¹⁹ road users on average would be made worse off with congestion pricing, with travelers having high values of time made better off at the expense of those with low time values, who are now made worse off. In the analysis based on a distribution of values of time: (1) the magnitude of the time saved from a trip by everyone is still the same; and (2) the toll that all road users face is the same as before. Now instead of the congestion toll being computed on the basis of a constant (marginal) value of time, the latter is being replaced by a weighted average of the (marginal) values of time, with the weights being the number of trips taken by those who use the road.²⁰ Precongestion pricing, at the margin, the motorist is indifferent between taking a trip at the traffic equilibrium q^0 ; he compares his willingness-to-pay with the (average) time cost of a trip, the comparison being a straightforward one. Postcongestion pricing at the

¹⁷ These terms belong to Zettel and Carll (1964). By contrast, Hau (2005a) uses economic efficiency analysis to formally derive the welfare impact of road pricing on the tolled and the tolled off, etc., in a comprehensive short-run/long-run framework, drawing conclusions that are opposite to theirs.

¹⁸ In the foreword to the famous U.K. Ministry of Transport paper (1964) on road pricing, Reuben Smeed explicitly states that “the panel *assumed* that the introduction of road prices would be accompanied by a corresponding reduction in existing taxes so that the motoring population as a whole would pay no more than it would otherwise have done” (emphasis added). In fact, however, the road use price is converted into a ‘tax’ in that the toll revenues collected typically gets deposited into the government’s coffers and, at least as far as motorists are concerned, vanishes altogether (see the reasons for the failure of the proposed Hong Kong’s electronic road pricing pilot system of 1983-5 in Hau (1990)).

¹⁹ Weitzman (1974) was apparently the first to note that the variable factor employed would be better off under a free access equilibrium in the classic tragedy of the commons. For the case of roads, it implicitly assumes a constant value of time.

²⁰ Mohring (1976, Chapter 4 and Appendix) discusses the notion of the weighted values of time in relation to the optimization and pricing of transport services. Here I apply the concept of the weighted values of time to the welfare impact of a congestion toll: both optimal and nonoptimal.

new equilibrium q' , however, while the motorist still makes a similar comparison at the margin, but with a distribution of the values of time, the motorist who stays and pays is likely to have a higher value of time.²¹ The conclusion reached before that all parties except the government are worse off as a result of the toll holds whether the optimum toll is computed on the basis of a constant value or a distribution of values of time. Assuming that the toll revenues confer no benefit on road users, as is often perceived and perhaps justifiably so, it is clear that gainers cannot use their gains to more than compensate the losers' losses, that is, using a straightforward application of the compensation principle in welfare economics (see [Boadway and Bruce \(1984, Article 4\)](#)). To illustrate, suppose that a rich person is willing to pay much more than a dollar of toll to save a little time. His gain would be insufficient to overcompensate the rest of the tolled—supposing, as before, that the toll revenue is siphoned off or gets buried in the Treasury. This is because that optimal toll was computed on the basis of a weighted average of values of time. If the optimal traffic flow is reached and yet those with high values of time are willing to pay considerably more for time saved than the optimal toll as well as being able to overcompensate those with low values of time, then the "optimal" toll must not have been at a high enough level and could not have properly reflected the weighted average of the values of time. The impact of imposing a weighted congestion toll is in effect to raise the toll that everyone faces, so that the gains to those with high values of time are obtained at the expense of those with low time values.²² The law of demand must be obeyed.

Note that the *incidental* time saved (of 4 min) on average that comes about by charging the *marginal* externality (of 10 min or, rather, its money equivalent) is always less than the latter because of the downward sloping nature of the demand curve. We ask therefore, at the aggregate or average level as opposed to operating at the margin, whether it is possible for the rich to overcompensate the poor and still be better off. The answer is in the negative because while some of those with high time values are willing to pay more than the weighted congestion toll for time saved (which for them the toll payment amounts to only a fraction of the value of time savings), those with low time values who are not willing to pay the average toll payment for the average amount of time saved still have to make payment (because their willingness to pay for a trip exceeds the final equilibrium price inclusive of the congestion toll, P'). Thus, on average and in the aggregate, the gainers could not overcompensate the losers when faced with a weighted average congestion toll. Do bear in mind that here we are confining ourselves to the tolled and not considering those who have already been tolled off, who are clearly worse off by revealed preference.

A follow-up question is whether or not the aggregate value of time savings to the tolled would be sufficient to more than compensate the welfare loss of the tolled off, at least in a hypothetical compensation sense. After all, an in-kind transfer of this kind could not be feasibly carried out because one person's time saved could not possibly become someone else's gain in time units. The answer is clearly in the affirmative since the amount of actual time savings comes about by curtailing the excess number of trips: $q^0 - q'$. The welfare loss is only that part of the loss in valuation of those trips to the tolled off that is over and above the tolled off's own time costs (of area $g + k$). Putting it another way, area $e + f$ is always greater than area d .

Before leaving the point that road pricing hurts most parties except the government, it is important to point out that there are cases—one of which is the case of hypercongestion—analyzed in [Hau \(2005a, Fig. 6\)](#) which shows that road pricing benefits *everyone*: all users as well as the government entity. This occurs when traffic density is so high (at the point V and beyond) that the rate at which one more vehicle entering an area is greater than the rate at which one more vehicle leaving it. The resultant throughput is lower, yielding the backward-bending portion of the average variable cost curve. The initial traffic equilibrium would be observed at the intersection point of a high demand curve and a point on the backward-bending portion of the average variable cost curve. Implementing congestion pricing in traffic bottlenecks such as this one proves most promising since everyone is made better off: a clear case of a Pareto improvement. In other words, hypercongestion yields a truly win-win situation even without compensation ([Hau \(2005a, Fig. 6\)](#)). While it is empirically testable but debatable whether the duration of these bottlenecks is persistent enough in particular cases to justify promoting congestion pricing principally on these grounds, the rationale seems clear in many of the more seriously congested situations as seen in many megacities worldwide. Even so, hypercongestion is not generally the case on which road pricing proponents have built their case.²³

Congestion Toll as a User Fee

A question that stems from the above analysis is whether or not there is a theoretical basis for *actual* compensation, as opposed to the *hypothetical* compensation principle of treating "a dollar as a dollar to whomsoever it accrues to" implicit in the evaluation of the welfare gain from congestion pricing. The answer is "yes" if one is not confined to the notion of marginal cost pricing in the short run *per se*.

The following article applies these principles to the problem of identifying an equilibrium for traffic allocation to roads in the short- and long run.

²¹ At the margin, the motorist is indifferent between driving and not driving: driving involves incurring the time cost of distance Tq' (i.e., travel time) plus the toll payment of distance YT whereas not driving involves saving his (private) resources of Tq' and toll expense of YT by forgoing any benefits from taking the trip. If the motorist were to undertake the last trip at the margin, other motorists in the traffic stream would bear the amount of YT in terms of time delay (which equals 10 minutes in our example above) and the road authority would reap the gain in revenue from the (unit) toll payment. By forgoing this last trip, the motorist actually yields time savings for everyone who continues to use the road.

²² One might wonder whether the rich or urgent users, broadly speaking, would be able to overcompensate the poor or more leisurely users when a small nonoptimal toll is implemented at the observed output level, q^0 . It is possible to imagine that under such a scenario the gainers would be able to more than compensate the losers since no constraint would be placed on the numerical value of the nonoptimal toll. For a very small nonoptimal toll, indeed the loss to the tolled off will be extremely small; the average value of time savings of those remaining is likely to far exceed the toll in a very congested situation.

²³ William Vickrey, by contrast, strongly advocates using hypercongestion to build the case for road pricing.

Introduction

In the previous article the theory of congestion pricing was developed to show how the application of road pricing could control congestion and achieve a welfare improvement. In this article, we develop the theory to show the equilibrium conditions for road traffic in the short- and long-run and subsequently show the effect of relaxing some of the assumptions.

Short-Run Equilibrium of Road Transportation

Thus, far we have characterized the nature of traffic congestion and discussed how its excess could be curtailed. Just as a truck whose axle weight damages the road—leaving behind potholes that raise vehicle operating costs and cause delays to other motorists—ought to be charged for the road damage inflicted, so also should a responsible road authority charge for the incremental external cost by equating the marginal cost of a trip to society to its marginal benefit. The rule is quite straightforward, and that is to always charge for the marginal external cost that a motorist rationally ignores, this regardless of the road infrastructure capacity. Given a particular level of travel demand, marginal cost pricing would call for a high congestion toll for a road with low capacity vis-à-vis a high one. One might ask, would not withholding investment in road capacity result in a congestion toll level considered by motorists to be too pricey? Posing the question this way suggests that an optimal investment in road capacity level exists: overinvestment in road capacity would possibly result in minimal congestion and a very low congestion toll. In contrast, underinvestment in road capacity would result in excessive congestion, calling forth an inordinate toll. In point of fact, up until now we had implicitly assumed a built-up road system that motorists utilize, as represented by adopting a given level of road capacity, say, at K' (see footnote 10 in the previous article): we are effectively in the short run. The short run is a time period during which some input, such as the capital input, could not be varied: the road, or associated transport infrastructure, is regarded as fixed exogenously at any point of time. A socially responsible road authority has to consider the fixed (opportunity) cost of constructing a road. The opportunity cost is the highest-valued use of the resource elsewhere when used here. In the absence of noncompetitive and external effects in road construction, the market price of the capital input used would be a good measure of the opportunity cost, which would include imputed interest on invested capital. As the fixed cost is a lump sum of money expenditure independent of output, the per-unit-of-time fixed cost of construction is depicted as a rectangular hyperbola in Fig. 1. The short-run average fixed cost (SRAFC), for a road with a given capacity, K' , is denoted by $SRAFC(K')$. It would be socially irresponsible for the road authority to merely minimize its dollar cost of road construction and provide a road with minimal capacity. To be socially accountable, the road authority as a producer of road capital needs to consider also the variable input supplied by its user: the time cost of the traveler. Thus the road authority sums up its per-unit-of-time construction cost, $SRAFC(K')$, with the traveler's (short-run) average variable cost, $SRAVC(K')$, to form the short-run average total cost, $SRATC(K')$, curve as shown in Fig. 1.

Here it comes in handy to view the traveler's dual role as a consumer–demander and producer–supplier of a finished trip. In order to decide whether or not to expand road capacity, the road authority compares the return on its facility, that is, the per-unit-of-time quasi-rent, with its per-unit-of-time capital cost. The quasi-rent—the difference of the full price of a trip less its average variable cost—turns out to be captured by the road authority via the instrument of a congestion toll.¹ As (economic) rent is a slippery concept, we can approach the problem of optimal road capacity provision by looking at the other side of the same coin: as a producer of road capital, the “revenue” received from the consumer as demander less the consumer as supplier of travel time input, in money terms, and the opportunity cost of road construction is the “economic profit”. The residual of quasi-rent less the opportunity cost is the economic profit, or, what amounts to the same thing, the economic profit is the per-unit-of-time optimal toll less the per-unit-of-

¹ ‘Rent’ is a payment to a factor of production over and above that which is necessary to draw forth its services and ‘quasi-’ refers to the fact that, if it earned no compensation, the flow of services from the fixed capital would be provided only until the road capital asset is depreciated (see Hau (2005a) and Mohring (1976, Chapter2)). Quasi-rent is the analog of producer's surplus in the input market.

Figure 1 Short-run equilibrium of a quasi-market road authority.

time fixed cost of road capital, starkly shown in **Fig. 1**. With the level of road capital stock, K' , being an arbitrarily chosen one, the equilibrium of a road authority behaving in an efficiency-enhancing competitive manner in the short run is shown as the short-run equilibrium of a competitive, or quasi-market, rather, road authority in **Fig. 1**. Given any level of road capacity such as K' , the congestion toll is the difference of $SRMC(K')$ and $SRAVC(K')$: τ' .

Long-Run Equilibrium of Road Transportation

We now ask, would a road agency behaving competitively by mimicking such economic efficiency, efficiency-enhancing pricing principles discussed thus far be able to sustain itself over the long haul? That is, does the “competitive” road agency’s revenues cover its cost of road provision in the long run? The answer is “yes” under certain conditions. When the road agency’s economic profit is positive, pursuing economic efficiency calls for the expansion of the capital stock of a road. *Per contra*, when the congestion toll revenue is less than the opportunity cost of road capital, the capital stock of the road should be lessened. Varying road capacity from a road initially with nonoptimal capacity, K' , to one that has optimal capacity, K^* , is precisely the process by which a competitive road transport agency would arrive at in the long run when road capacity is optimized.

Optimal Capacity

How the road agency arrives in long-run equilibrium relies on the correct signal being emitted by optimally setting the full price of transportation to the short-run marginal cost of a trip for any given road capacity. This is how the quasi-market mechanism works: when economic profit is positive, starting off with an arbitrary, nonoptimal road capacity level that is low, say, K' (as shown in **Fig. 1**), the capacity of the road should be enlarged and the road partially decongested until economic profit is eroded. If so, the corresponding optimal price would be lowered from P' to P^* , output would rise from q' to q^* , the minimum level of traffic before congestion sets in would rise from $t^M M$ to $t^M M^*$. When economic profit is nil, the level of capacity is optimized, at an expanded level

of capacity at K^* . The minimum of $SRATC(K^*)$ would be achieved at N^* after a proportionate increase in capacity to K^* . At zero economic profit, the per-unit-of-time quasi-rent, QR^* , is equal to the per-unit-of-time opportunity cost of road construction, $SRAFC(K^*)$, that is, the optimal toll, τ^* , covers the per-unit-of-time cost of optimized road capital, $SRAFC^*$, as plainly shown in Fig. 1. The total congestion toll revenue collection for the optimized road capacity K^* would exactly cover the total opportunity cost of road construction. Equivalently, when economic profit is nil, long run equilibrium is reached. This path-breaking finding is known as the Mohring–Harwitz theorem, selffinancing or cost-recovery theorem. For the socially amenable road authority behaving in such a quasi-competitive market, note that this result would come about under stringent but plausible conditions of constant returns to scale.² When all inputs are proportionately increased, the same applies to output and costs also, resulting in a horizontal long-run average total cost (LRATC) that wraps itself as an envelope around all the minimal points of $SRATC(K')$ and $SRATC(K^*)$. Hence the long-run marginal cost (LRMC), is flat too and coincides with the LRATC curve (see Fig. 2).³ At whatever desired level of output a road with a particular capacity will have an associated SRMC curve associated with it that crosses the LRMC curve.

We ask what equimarginal principle is met when we try to determine the optimal road capital stock. Our objective now has turned to maximizing the net benefits of travel over the long run. Beforehand, with road capacity fixed at any given level, short-run net benefit maximization calls for the road authority's imposition of a congestion toll *wedge* when applying marginal cost pricing. In the long run, highway capacity can be relaxed and K varied as time passes. Since the benefits of travel do not depend on the capacity *per se*, long-run net benefit maximization implies cost minimization. The road authority's task is straightforward: jointly minimize the traveler's time cost and the road authority's capital cost of road capacity, KC . Given an arbitrary output level, the road authority aims to vary road capacity to the point where the marginal benefit of expanding capacity in the form of marginal savings in external time cost is equal to the marginal cost of road capacity.⁴ This is the Optimal Capacity Rule, our Second Optimality Rule. The net benefits of travel are not only maximized at any point in time, they are maximized in the long run by varying the road capacity level even if we had started off with a nonoptimal capital stock, K' . The per-unit-of-time quasi-rent earned from society's fixed investment in road capacity, QR^* , as captured by the per-unit-of-time optimal congestion toll, τ^* , is the same as the per-unit-of-time opportunity cost of road capital, $SRAFC^*$ (see Fig. 2). When overall constant returns is satisfied by a combination of the twin conditions of constant returns, the quasi-market mechanism of congestion tolling says that the size of road capacity should be adjusted to the point where optimal quasi-rent and average fixed cost is the same: $QR^* = SRAFC^*$, both on a compatible unit basis. This means that the total revenues from congestion tolling just cover the total economic cost of road construction (Fig. 2). This is the celebrated selffinancing or cost-recovery theorem advanced by Mohring and Harwitz, which has spawned half a century of research in transportation economics. The model is generalizable to all congestion-prone transport infrastructure networks such as airports and ports, for instance (Bennathan and Walters, 1979; Mohring, 1984; Morrison, 1983; Verhoef and Mohring, 2009; Zhang and Czerny, 2012).⁵

²To obtain the famous selffinancing result in roads, it turns out that two technical assumptions about constant returns are needed (Mohring and Harwitz (1962, Chapter 2)): Constant returns to scale in road construction (i.e., output is doubled when all inputs are doubled). We assume that the construction cost of road capacity, KC , defined to include capital, depreciation and "invariant" maintenance costs, is directly proportional to the capacity of the road alone, K , i.e., $KC(K) = aK$, where a is a constant, following Keeler and Small (1977). ("Invariant" maintenance costs are those nontraffic-dependent maintenance costs due to Walters (1968, p. 23).) The lane-width, treated continuously, could be viewed as a simple measure of capacity. Doubling road capacity, K , results in the construction cost being doubled. Technically, KC is homogeneous of degree one in road capacity. Diagrammatically, the rectangular area of road construction and invariant maintenance costs is doubled. When all inputs are doubled and output is doubled, we say there is constant returns to scale, and, if cost is doubled also, we say there is neutral or zero economies of scale. When the input market is assumed to be competitive, constant returns to scale in construction is synonymous with neutral economies of scale in construction. i) Constant returns to scale in road use (i.e., the travel time cost function remains unchanged when inputs and output are doubled). Clearly the time cost function, $AVC(q, K)$, rises with output but falls with capacity, *ceteris paribus*. Technically, AVC is homogeneous of degree zero in output and capacity. Diagrammatically, when capacity and output are doubled, the rectangular area of time cost double, whereas the per-unit-of-time time cost remains the same. Constant returns to scale in road use is synonymous with neutral economies of scale in road use. This technical condition could be achieved, for instance, by usually specifying that the travel time function depends on the volume-capacity ratio, q/K , as follows: $AVC(q/K)$. This condition is also known as constant returns to scale in congestion technology (Small (1992, Chapter 3)). e had argued that the (average) vehicle operating cost is independent of output. We further assume that the variable road maintenance cost too is independent of output. Together with the construction cost and invariant maintenance cost being proportional to capacity expansion, the average total cost could also be written as: $ATC(q, K) = ATC(q/K)$. These two mathematical conditions are vital to Mohring and Harwitz's theorem (1962, pp. 85–90). In actuality, it is the combination of both conditions that yields the exact selffinancing theorem. Assuming input prices remain the same, the condition of constant returns to scale is synonymous with neutral economies of scale. Small (1999) shows that the one-to-one correspondence between the production function and the cost function no longer holds when there is a rising supply curve for a capital input, say. We implicitly assume that prices in the input market, like the output market, are determined competitively, which allows us to use the production function and the cost function interchangeably.

³Pictorially, N and N^* are of the same height in Figs. 5 and 6. This comes about because constant returns imply a horizontal LRAC which envelops all SRAC curves regardless of the capital stock.

⁴Formally, cost minimization yields the following expression: $-q \frac{\Delta AVC(q, K)}{\Delta K} = \frac{\Delta KC(K)}{\Delta K}$ his says that the marginal decrease in travel time due to an incremental increase in capacity, $\Delta AVC(q, K)/\Delta K$, would have to be multiplied by all the vehicle trips behind it, q . With the negative sign, the inverse relationship between AVC and K turns the entire expression into a positive magnitude on the left-hand side. Intuitively, the left-hand side gives the marginal benefit of increasing capacity. The right-hand side gives the marginal increase in the capital cost, $\Delta KC(K)/\Delta K$, due to an incremental increase in capacity. This is the first-best Optimal Capacity Rule. Here capital cost includes both the cost of road capital and the invariant maintenance cost of road capacity. The capital cost, KC , of road capacity is in per-unit-of-time dollar terms, $KC(K)$.

⁵The Mohring–Harwitz theorem also reconciles the long-standing debate of short-run marginal cost pricing versus long-run marginal cost pricing at the World Bank. In the political economy arena, proponents who favor using pricing to tackle congestion relief favor short-run marginal cost pricing or congestion charging whereas supporters concerned about the cost recovery of a road agency in an increasingly tight fiscal environment favor long-run marginal cost pricing as all costs, including capital cost, are charged. Both views are in fact reconciled here. The correct dictum is to pursue short-run marginal cost pricing over the long run, first in the short run and then in the long run. Society's welfare would thereby be maximized. Pursuing long run marginal cost pricing under constant returns would be charging the same price regardless of the level of demand; it is in effect implemented by a fuel tax set to cover all road costs. Under this latter scenario congestion externalities would be excessive and road use inefficiently utilized.

Figure 3 Economies and diseconomies of scale in the provision of road capacity with the growth of travel demand.

demand of q_3^d , the diseconomies of scale kick in. When traffic is low, a two-lane road is built. Increasing returns to scale due to (engineering) capacity clearly comes about when going from a two-lane road to a four-lane one. Beyond six or eight lanes, decreasing returns are likely to set in. In between is the case of constant returns to scale. Another way of looking at the three stages of traffic growth is to just treat each stage as a separate scenario independent of one another.

Consider first the case of decreasing returns of scale, for which the demand is high, at q_3^d , and where the long run marginal cost rises above its corresponding average cost curve. This scenario could come about because input is being bid up, resulting in a rising opportunity cost of capital and a divergence of marginal and average cost even in the long run. Pursuing short-run marginal cost pricing over the long run would definitely result in an economic profit. Urban roads with heavy traffic would characterize this region of diseconomies. Because downtown areas have high imputed land rents leading to high capital cost of roads, congestion pricing would mean that economic profits would be generated due to the increasing divergence of the pair of long run cost curves. Note that the optimal capacity chosen in the long run would be that capital stock that is less than the capital stock associated with the optimal output (see Hau (2005a, Fig. 4)). Writ large, decreasing returns to scale is likely to prevail not only with an urban road but with an urban road network. For instance, as the number of roads is doubled, the number of intersections and hence waiting times is quadrupled, a point attributable to William Vickrey (Mohring (1976, article 12), Hau (2005b, Fig. 3)). Either installing more traffic lights or building overpasses and interchanges would contribute toward bidding up the opportunity cost of land, a key ingredient in the cost of road capital, resulting in both rising average and marginal costs in the long run as well as their associated congestion tolls. These economic profits could naturally be used to finance the improvement of an alternative, being a cash-strapped public transport system, as those on public transport—both the tolled off and the tolled on—whose welfare would be well positioned to be improved.

Under the condition of increasing returns to scale or economies of scale, pursuing short-run marginal cost pricing over the long run would involve persistently incurring economic losses. Rural roads with low traffic would characterize this region of scale economies. Deficits would most likely prevail due to the technical condition of increasing returns to scale. The case of increasing returns is merely a case of insufficient demand, a point clearly seen in the economies of scale region where there is low traffic vis-à-vis the road capacity. The presence of scale economies would naturally beckon the road authority to seek economically efficient subsidization out of the public treasury. Before an optimal per unit subsidy is sought from the authority, a benefit-cost test needs

to be applied here, that is, the total benefit from travel must exceed the total cost from travel evaluated at the efficient output level, by adopting the standard compensation principle of treating a dollar of benefit or cost being a dollar regardless of to whomsoever it accrues to. Evaluated at the efficient output level,⁷ the optimal per unit subsidy is set at the difference of the long-run average cost over the LRMC to cover the per unit economic loss in Fig. 3 (see Hau (2005a, Fig. 5).)

Relaxation of Assumptions

The Mohring–Harwitz theorem is arrived at by assuming that the road authority mimics the workings of a competitive market by pursuing optimal pricing of road use and achieving optimal capacity of the road. By taking road capacity as given in the short run, road use is optimized by short-run marginal cost pricing. By optimizing road capacity in the long run, road use is doubly optimized. In so doing the sum of consumer's surplus and producer's surplus of the community being maximized would be achieved. The innovation of the economic approach adopted here, due to Professor Herbert Mohring (1994, Introduction), is to view the buyer of a transport service—the demander—as playing a dual consuming and producing role, bringing transport into the mainstream of microeconomic analysis and casting the use of road transport in a standard economics short-run and long-run framework for any good or service.

Besides considering all three cases of returns to scale, some simplifying assumptions of the Mohring–Harwitz model could be further relaxed. If the road authority mistakenly imposes a balanced-budget restriction when there are in fact increasing or decreasing returns to scale in road capacity, it still turns out that the selffinancing result is quite robust (Verhoef and Mohring, 2009). When land input price is considered when demand for road construction increases in an urban area, the exact selffinancing result still holds (Small, 1999). Verhoef and Mohring (2009) consider the robustness of the selffinancing theorem with various second-best scenarios using a simulation model.

1. *Static demand and time-varying demand:* It could be shown that the more realistic time-varying travel demand patterns that occur throughout the day—as opposed to the static one-period case—could be handled by varying the tolls optimally over time (Arnott and Kraus, 1998). Aggregating the time-of-day tolls over the day, month, and year would necessitate taking the present discounted value of the captured quasi-rents and comparing costs on the same per-unit-of-time basis.⁸ With growing traffic under constant returns to scale, the static selffinancing result is shown also to work, as shown by Arnott and Kraus (1998).
2. *Single road and road network:* When going from a single road to a full network, the selffinancing result holds for every individual road link in a road network, provided that all parts of the network are optimally priced (Yang and Meng, 2002).
3. *Variability of road thickness and road maintenance cost:* Heavy vehicles such as trucks and buses damage roads. When an additional attribute of a road—its thickness—is considered, its optimal durability needs to be considered. The optimal durability rule, a third rule, says that a road is optimally strengthened by investing up to the point where the marginal cost of durability is the same as the savings in vehicle operating costs to other motorists plus the associated savings in maintenance costs due to a thicker pavement (Hau, 2005b). When the road durability choice and road maintenance cost are considered, the selffinancing result still goes through. Under the conditions of constant returns to scale and road use, the efficient congestion toll will yield revenues that cover the capital cost of the highway but only the invariable (or nonallocable) portion of road maintenance cost attributable to weather (Newbery, 1989, Proposition 1). It then follows that the optimal road user charge, that is, the optimal congestion toll-cum-road damage charge, will then yield revenues that cover the capital cost of the road and the total road maintenance cost in a constant returns world (Newbery, 1989, Proposition 2). In other words, the optimal congestion toll covers both the capital cost of the road and the nonallocable fraction of road maintenance, whereas the allocable fraction of road maintenance is still chargeable to traffic loadings via the average variable road maintenance cost component per equivalent standard axle load (ESAL). In this way, the total expenditure on road maintenance is fully recoverable.
4. *Divisibility of road infrastructure:* Far from being perfectly divisible, in reality indivisibility is present in roads. A road requires a minimum lane-width of 12 feet, for instance, to accommodate an automobile, and a two-lane road for bi-directional travel. Coupled with the need for shoulders and drainage ditches, a significant proportion of road provision involves dead space. It turns out that indivisibility complicates the consideration of scale economies and economic losses.

With almost perfect divisibility, decreasing returns to scale would still yield economic profits at all output levels. With indivisibility, the upward-sloping LRMC hosts a series of finite, short-run marginal cost curves and is saw-toothed-shaped with the switchover (kinked) points occurring where the short-run average total cost curves cross one another (Hau (2005b, Fig. 4)). Any output level whose intersection of the short-run marginal cost curves (which cut the LRMC curve) greater than the corresponding short-run average cost curve would yield profitability and else not. However, the extent of profitability is lessened the greater the indivisibility due to the falling portions in the saw-toothed long-run average cost curve, forcing such roads to experience swings of losses and profits.

⁷ Applying short-run marginal cost pricing over the long run, we set the full price of a trip, P , to long-run marginal cost. The efficient level of output is found at the intersection of the demand curve q_1^d, q_1^d and the corresponding long run marginal cost curve. To be considered economically viable, the total benefit must exceed the total cost of travel at the efficient output level where the optimal capital stock is chosen. Note that there is excess capacity as the optimal capital stock selected should be higher.

⁸ Hau et al. (2011) estimate efficient time-varying tolls for Hong Kong's only three tunnels traversing the Victoria Harbour using hourly data from the Transport Department.

In contrast, with almost perfect divisibility, increasing returns to scale would still yield economic losses everywhere. With increasing returns, by symmetry; however, the loss regions are lessened the greater the extent of indivisibility. Just as large fixed costs of construction contribute to periodic losses, a steady increase in travel demand vis-à-vis the prevailing road capacity would contribute to periodic gains even in the presence of increasing returns. Hence the presence of indivisibility results in roads experiencing swings from losses to profits regardless of the extent of scale economies. The standard result of decreasing returns to scale being synonymous with profitability and increasing returns to scale corresponding with losses does not hold when indivisibility is taken into account (see [Hau \(2005b, Figs. 4 and 5\)](#)).

Empirically, [Keeler and Small \(1977\)](#) found that constant returns to scale exists in the San Francisco Bay Area. In *The Economics of Urban Transportation*, [Small and Verhoef \(2007, p. 112\)](#) conclude that:

“Altogether, the evidence supports the likelihood of mild scale economies for the overall highway network in major cities. Scale economies are probably substantial in small cities in which one or two major expressways are important, and may disappear altogether in very large cities where expanding expressways is extraordinarily expensive due to high urban density.”

Still, on top of the high opportunity cost of land in urban areas leading to a high cost of road capital, Vickrey's reasoning that there are considerable diseconomies of scale associated with an urban road network based on the geometry of road network would likely yield an urban road network that is economic profit-making.

Introduction

In the previous two chapters the theory of marginal cost pricing has been applied to the use of roads under congestion and to determine the equilibrium use of road networks in the short- and long-run. In order to get a full picture of the application of pricing as part of an overall approach to urban transportation it is necessary to apply the same principles to public transportation. This chapter assumes an understanding of the basic principles behind the application of marginal cost and congestion pricing from the previous two chapters.

An Analytical Framework for Pricing Public Transportation Use

The pursuit of marginal cost pricing shall now be extended from private transport to public transport. It is a truism that the accounts of public transit agencies are typically in the red, the shortfall of which requires public sector intervention and support. Local public transit, be it bus or rail, is unsustainable for several reasons. First, transit is subject to substantial economies of scale. Basing transit fares on average cost would result in fares that are higher than are desirable efficiency-wise. In the presence of increasing returns to scale, the marginal cost pricing of public transport, while efficient, results in financial losses that cannot be sustained. The absence of the marginal cost pricing of transit's competing mode—the ubiquitous private car—means that private transportation or road use is overused. Consequently, excessive automobile traffic exacerbates the financial losses of public transit agencies by siphoning much needed revenue passengers away.

Indeed, the classic justification for subsidizing public transport is based on second-best pricing, that is, negatively pricing public transportation because private transportation is implicitly subsidized in the absence of congestion pricing. In this way, it is sometimes argued that a rough balance between mass transit and private transportation would therefore surface. Yet, when the cost of implementing congestion pricing falls due to the declining cost of electronic technologies over time, the first-best pricing of private transportation has now proven enticingly feasible more than ever.

We have shown that long run net benefit maximization of highway-derived travel implies cost minimization and that the road authority's task is thus to trade off the traveler's time cost and the road authority's capital cost of road capacity. We next consider a socially responsible public transport agency interested in minimizing costs between two alternatives by adopting a back-to-back diagrammatic analysis for doing so. The analytical and geometric framework elucidated here and paradoxes advanced below follow the works of Nash (1976), Mogridge (1990a, 1990b), Small (1992), Arnott and Small (1994), Vickrey (1980, 1994) and Ding and Song (2012). Only by marginal cost pricing both private and public transportation would the sustainability of public transportation—from financial all the way to environmental—be within reach.

We extend our one-market framework of a single road to the simplest of a road network: the classic case of two roads. By way of historical background, a debate took place in the 1920s between Cambridge Professor Arthur Cecil Pigou and Chicago Professor Frank Knight that yielded the archetypal two-road case. Pigou considered the case of two public roads connecting point A to point D: one road is narrow, direct, straight and smooth, whereas the other is wide, long, circuitous and bumpy (see Fig. 1).

"Suppose there are two roads, ABD and ACD both leading from A to D. If left to itself, traffic would be so distributed that the trouble involved in driving a 'representative' cart along each of the two roads would be equal. But, in some circumstances, it would be possible, by shifting a few carts from route B to route C, greatly to lessen the trouble of driving by those still left on B, while only slightly increasing the trouble of driving along C. In these circumstances a rightly chosen measure of differential taxation against road B would create an 'artificial' situation superior to the 'natural' one. But the measure of differentiation must be rightly chosen."

A.C. Pigou, *The Economics of Welfare*, 1st edition, 1920, p. 194.

Figure 1 Pigou's classic two-road case.

A narrow road is short and direct and therefore fast but it has limited capacity; it attracts drivers eyeing for the fastest route. With many drivers taking the low-capacity road, congestion sets in quickly and the travel time, or time cost in money terms, rises geometrically (see Fig. 2A). A wide road is long and circuitous and therefore slow but it has ample capacity. The traffic on such a winding but high-capacity road is uncongested, with the travel time cost of a trip remaining the same throughout at AVC (see Fig. 2B).¹ Clearly drivers jockeying for the quickest route will divert to the road that is faster until it is just as fast, or as slow rather, as the narrow road. With each driver basing his decision solely on how long a time it takes for him to traverse that road, equilibrium will be reached where the travel time cost of a trip is the same on each road:

$$AVC_N = AVC_W$$

where AVC_N refers to the Average Variable Cost of trip taken on the Narrow Road and AVC_W refers to the Average Variable Cost of trip taken on the Wide Road. Given total traffic, Q_T , and each individual driver behaving rationally in a cost-minimizing manner on each road, the traffic equilibrium for this simple road network—the so-called User Equilibrium (U.E.)—will be reached as seen in Fig. 2C.² With two built roads, the intersection of AVC_N and AVC_W determines the short-run equilibrium: $SRAVC_N = SRAVC_W = AVC$, where AVC is the (initial) equilibrium average variable cost and the total traffic level of Q_T is distributed between equilibrium traffic on the narrow road, Q_N , and equilibrium traffic on the wide road, Q_W , at $Q = (Q_N, Q_W)$.

It is Knight's characterization of the conditions of such a traffic equilibrium for the two-link road network that was a precursor for what civil engineer Glenn Wardrop (1952, pp. 344-5) refers to as his first criterion of determining the distribution of routes based on travel times:

"The journey times on all the routes actually used are equal, and less than those which would be experienced by a single vehicle on any unused route."

Wardrop's first principle of route choice, widely referred to as User Equilibrium (U.E.), is also known as (selfish) Wardrop Equilibrium, the properties of which is that either of the two routes taken would end up being the same average travel time. If a route, say a third route, was not used, then that route must have a higher travel time; if not, there would be some traffic diverted to that third route. Wardrop's equilibrium and Knight's traffic equilibrium are the same, with the former expressed more formally in travel time units and the latter expressed in time cost units. We shall simply refer to both as User Equilibrium (UE) in our diagrams.

Further, Knight took Pigou to task by arguing that the introduction of a differential tax is misplaced because competition results in economic efficiency. Note that Knight's results are predicated upon the assumptions that: (1) road ownership is private and property rights are clearly delineated; (2) competition in road prevails and (3) scale economies are absent (Knight (1924), Hau (2005a, footnote 7)). However, even though Pigou was in fact considering the case of public roads and not private ones, regrettably Pigou withdrew the two-road case, now made famous, from subsequent editions of his book. Ever-present public roads the world over mean that negative externalities abound and the so-called "Pigouvian tax" or "Pigou tax"—attributed to none other than Professor Pigou himself—is indispensable in paving the way forward.³ After all, with the public sector being predominantly responsible for road provision and in spite of its monopoly position, it is the task of a benevolent road authority to mimic a competitive economy's efficiency-enhancing aspect by introducing a Pigouvian toll, more commonly known as a "congestion toll".

¹ Pigou and Knight assume that the wide road has sufficient capacity to handle total traffic (Knight (1924, Charts A, p. 588)).

² The term "user equilibrium" used here was subsequently attributed to Wardrop in 1952 based on his first criterion. Wardrop considered the general case of route choice with multiple routes whereas Pigou and Knight considered two routes in the 1920's.

³ We shall reserve the term 'Pigouvian tax' to include other externalities such as pollution on top of congestion. The term 'congestion tax' is a misnomer because it suggests that it is a governmental tax on congestion raised presumably for revenue purposes when it is clear that we should designate it as a 'congestion toll' as it is a price on congestion.

Figure 2 A back-to-back diagram of a narrow and wide road.

More occurrences of gridlock mean that there is a call for road capacity expansion of the fast road with either road construction or improvement. Would traffic woes be reduced? Following a lane expansion, say, the jump in traffic speed and a substantial improvement in travel time mean that traffic from the alternate wide route is attracted to the narrow road. The increase in road capacity is depicted by a horizontal fanning out of the average variable cost curve from AVC_N to AVC'_N (Fig. 3A).⁴ The resulting traffic equilibrium means that the expanded narrow road is now just as congested as before, with traffic equilibrating at the original average travel time cost of AVC^0 (Fig. 3B). The distribution of traffic has shifted from the wide road, Q , to the expanded narrow road, Q' . Road capacity expansion appears to be short-lived, a result known as the Pigou–Knight paradox. One way of overcoming the problem is to plow in a considerable amount of road investment resources so that the expanded narrow road is able to absorb the combined traffic of both roads to the point of being uneconomical at AVC' in Fig. 3B (see [Arnott and Small, 1994](#) and [Ding and](#)

⁴The fact that the shift in the average variable cost curve is anchored at the vertical intercept means that the average variable cost of a trip reflects the assumption of constant returns to road use in Figs. 4 and 5. For instance, the typical lane capacity of 1600 vehicles per hour per lane remains roughly the same when expanding from a 4-lane road to a 6-lane road.

Figure 3 A Paradox and Downs's Law. (A) Downs's Fundamental Law of Highway Congestion Pigou–Knight Paradox: Route Convergence; (B) Overexpansion in the Presence of the Pigou–Knight Paradox.

Song, 2012 for numerical examples).⁵ It is uneconomical because a lowering of the average time cost from AVC to AVC' would suggest that the initial road had been underbuilt. Any optimally designed and used road should have *some* nonzero amount of congestion.

Anthony Downs (1962, 1992) advances the proposition that an increase in traffic capacity on commuter highways in urban areas results in an increase in urban travel demand during rush hour that erodes much of the capacity-enhanced traffic improvement. He calls it “the law of peak-hour expressway congestion” and “the iron law of congestion”, which states that, colloquially: “If you build them, they will come” as in the movie *The Field of Dreams*, 1989, starring Kevin Costner. The fundamental law of traffic congestion phenomenon arises because demand that has been suppressed up till now—otherwise known as latent demand—as a result of peak-hour congestion itself is released as soon as the traffic situation has improved.⁶ After all, we all opt to travel at our most convenient

⁵ The Pigou-Knight paradox is sometimes referred to as the Pigou-Knight-Downs paradox.

⁶ Downs's law is actually a transport example of a more general principle known in the literature as the tragedy of the commons: a resource that is unowned and unpriced would attract overexploitation and use.

time by our most favored mode and route were it not for having forced to queue up. So any betterment in travel time due to capacity enhancement will persuade hitherto early birds, for instance, to commute later and closer to their official work start time. Traffic will hereby increase until congestion worsens to a tolerable level—such as to that of an inferior local arterial—unless some sort of traffic restraint is imposed. In the Pigou–Knight paradox as depicted in the two-road case of Fig. 3A, the latent demand comes from the alternate route—the wide road—which by Pigou’s assumption has plentiful capacity.⁷ Downs coins this case “route convergence” or “spatial convergence”, the first of what he calls “triple convergence” occurring on a typical peak-hour weekday. Route convergence occurs because motorists would converge onto the most accessible and quickest route, thereby congesting it; motorists who formerly used alternate routes would search for the “best” route spatially. It is said that a variant of Say’s law in urban traffic therefore holds: (new) supply creates its own demand.

So how do we tackle this traffic conundrum? As in our one-market case, the economically efficient solution is to *price* for road use at marginal cost. For optimality, total travel time for the system via both routes has to be smallest, a result known as a System Optimal in time units or Social Optimum (S.O.) in money terms. Cost minimization for society could be met when the following condition holds for the case of two roads even when both are congested (Beckmann et al., 1956, Chapter 4)):

$$MC_N = MC_W$$

As before, the equimarginal principle would suggest that total travel cost would be lowest if the incremental costs end up being the same; else not. Civil engineers attribute this result to Wardrop’s (1952, p. 345) second principle:

“The average journey time is a minimum . . . the second criterion is the most efficient in the sense that it minimizes the vehicle-hours spent on the journey.”

Intuitively, if the marginal travel time of undertaking a trip via one road is lower than that of the other, total travel time for society could be lowered by moving over from one road to the other road until there is no longer a difference. Total travel time minimization could not be attained if the marginal cost of a trip undertaken via one road is higher than that of the other as a trip could be diverted from the higher cost road to a lower one with travel time saved.

When there is no divergence of the Average Variable Cost and the Marginal Cost of undertaking a trip via the wide road, no congestion toll needs be imposed. On the other hand, with a divergence of the Marginal Cost and the Average Variable Cost of undertaking a trip via the narrow road, a congestion toll τ^* needs to be imposed (Fig. 4). With marginal cost pricing, the collected

Figure 4 Wardrop's 2nd Principle.

⁷The analysis would still go through even if total traffic would result in congestion for both routes.

Figure 5 Reaping of the Bona Fide Benefits of Congestion Pricing

congestion toll revenues are simply the recouped quasi-rents. Note that the reaped travel time savings of a trip stem from applying marginal cost pricing, which lowers the Average Variable Cost of a trip from AVC to AVC^* . When multiplying the difference of the saving in Average Variable Cost by Q_N' , the traffic on the narrow road in the final equilibrium, the travel time savings result and is depicted as the shaded rectangle in Fig. 4.⁸ The congestion toll is able to—as if by magic—effectuate the travel time reduction of a trip via the narrow road by simply emitting the correct price signal to travelers to substitute money for travel time with the correct toll charged at the margin. Here we clearly see that it is the entire resultant travel time savings that is the *bona fide* benefits of congestion pricing; the road authority's congestion toll revenue collection as a transfer payment is further clarified. An alternative calculation of the resulting time savings: the welfare gain from the congestion toll, could be obtained by viewing the shaded triangular area below the Marginal Cost of undertaking a trip via the narrow road bounded by Q^0 and Q' .⁹ Looking at the argument the other way around, by *not* pursuing marginal cost pricing, the time cost incurred via both routes is the large rectangle in Fig. 4 and the difference in not going from U.E. to S.O. is the foregone shaded rectangle of time savings. Equivalently, the shaded triangular area is now the welfare loss of not going from U.E. to S.O.

So is road capacity expansion beneficial in such a case of marginal cost pricing? The answer is shown in Fig. 5, where the proportionate shifting of the pair of Marginal Cost and Average Variable Cost curves due to capacity expansion of the narrow road results in a proportionate increase in travel time savings.¹⁰

Duranton and Turner (2011) uses data from American cities to confirm Downs's "fundamental law of highway congestion". They find that vehicle kilometers traveled (VKT) increases one for one with interstate highways increase. They also uncover suggestive evidence that the law extends to major urban roads. They conclude that expansion of interstate highway and major urban road capacity is unlikely to bring about congestion relief. Surprisingly, the additional traffic does not come from other road types but from increased driving, among other factors, suggesting the presence and scale of induced demand.

The lesson here to be drawn here is that only by pursuing marginal cost pricing, or congestion pricing in the context of a road network, would road capacity expansion yield an increase in travel time savings or a gain in welfare without rent being dissipated. With proper pricing, the Pigou–Knight paradox and Downs's fundamental law of traffic congestion are now overcome.

Base Case

One key feature of public transport—both bus and rail—is that it is subject to increasing returns to scale due to large fixed cost, a feature we incorporate in our Base Case. Rail transportation is particularly capital-intensive and would require sufficient patronage

⁸The final equilibrium of the distribution of traffic is at $Q' = (Q_N', Q_W')$ in Fig. 4.

⁹The shaded triangular area and the shaded rectangular area is easily shown to be equivalent by first principles.

¹⁰While road expansion is no longer self-defeating, whether or not a road should be expanded should be governed by standard benefit-cost calculus (Hau, 2005b). As a transfer payment, the congestion toll revenues should be considered once but not double-counted (Mohring, 1993).

for it to survive. Although bus transport is less capital-intensive than rail, it too has to grapple with the issue of a declining average cost curve. In the long run, when a bus transit agency is allowed to vary the size of its capital stock, the average cost is lower with increased use. This means that the marginal cost of catering to more users lies below the average cost, frustrating a transit firm's efforts to survive in a market environment. On one hand, if average cost pricing were pursued, one financially breaks even but results in economic inefficiency. Imposing a hard budget constraint has a distinct advantage of incentivizing managerial efficiency in the transit agency. On the other hand, if marginal cost pricing were adopted, a transit agency will not be able to break even. After all, the case of economies of scale on the cost side, or increasing returns to scale on its production counterpart, is in fact a case of insufficient demand. Hence a Pigouvian subsidy or optimal per unit subsidy imposed on the user side is warranted following marginal cost pricing. But coming up with the funds to subsidize public transport involves considering the marginal cost of public funds that may make the economic case more difficult (Vickrey, 1980).

Another economic rationale in support of public transportation is due to Mohring (1963, 1970, 1972) and Turvey and Mohring (1975). Scheduled public transport differs from private transport in that the constant returns to scale condition does not hold. Suppose bus travel demand is doubled and if a transit agency were to respond by doubling the number of buses to be run, costs would appear to double and average costs would remain the same *prima facie*. However, with bus frequency doubling as a result, the waiting time is halved. Hence, the short-run average variable cost of a trip is lowered not only for the new arrivals, or "external" users rather, but also for the existing, or "internal" users, leading to a declining long run average cost curve and a long run marginal cost curve that lies below it at any output level. First observed by Professor Mohring, this effect is coined the Mohring effect in public transportation. The standard Short Run Average Variable Cost and Short Run Marginal Cost curves for bus transportation—which reflect elements internal to the bus firm and the tripmaker—rises, reflecting diminishing marginal productivity with respect to its own output of bus travel, but the Long Run Average Cost and Long Run Marginal Cost curves for bus travel—which reflect elements external to the transit firm but, because of the positive technological external economy engendered from more frequency, still internal to the industry as a whole—decline. This characterization is basically nothing more than the "system economy of scale effect" in microeconomics. Thus another first-best argument based on congestion pricing principles is brought forth to achieve economic efficiency on top of the traditional scale economy argument.

Given the fact that resource mobilization is increasingly difficult in a globalized world of financial shocks and pandemics, the question is how to come up with the funds to finance public transport. Putting it another way, the above considerations may lead one to wonder, how would transit agencies attract more users and become less cash-strapped? We shall appeal to various paradoxes to provide some guidance.

Consider a stylized urban transportation system where auto is the archetypal private transport mode and bus is the archetypal public transport mode. We can feature the salient aspects of urban transportation with a simplified model by depicting a rising Short Run Average Variable Cost curve for Auto as it faces diminishing marginal productivity and a falling Long Run Average Cost curve for Bus due to both aforementioned scale economy theories. By following the same reasoning as before with the two-road case, adopting Wardrop's 1st Principle on the behavior of both the auto and bus user would suggest that the condition for a new User Equilibrium is as follows (Fig. 6):

$$AVC_A = LRAC_B (= SRAC_B)$$

Figure 6 Scenario 0 Base Case of Average Variable Cost Pricing: $AVC_A = LRAC_B (= SRAC_B)$ Wardrop's 1st Principle

Figure 7 Downs–Thomson Paradox.

The rightly-chosen firm size that is determined by a bus agency is at the equilibrium traffic level of distribution of Q_B , where the *de facto* traffic distribution is: $Q = (Q_A, Q_B)$ at the status quo.¹¹ Note that at any point in time, one is always operating a particular firm size so the optimal firm size would be associated with the representative Short Run Average Cost curve for Bus, $SRAC_B$, tangent to the $LRAC_B$.¹² This is Scenario 0, also labeled as the Base Case, which I refer to as Average Variable Cost Pricing since at user equilibrium the average cost of a trip by either auto or bus is set equal to one another.¹³

Consider an increase in road capacity in the presence of both private transport and public transport. Private transport users, being the lion's share of road usage and the main beneficiaries of road expansion, benefit more; public transport users benefit too. Notice that an increase in road capacity now has a considerably greater impact—but negatively—on public transport than in the classic two-road case. This is because public transport relies on a large number of users to avoid being in the red. However, private transport, with its superior convenience and flexibility, outcompetes as well as siphons away much needed revenue passengers from public transport. Public transit agencies respond in two ways, both of which are detrimental to their own survival. With less passengers, transit agencies resort to raising fares to break even, likely leading to an even more of an exodus. And with less passengers, agencies cut transit frequencies to save on costs, which exacerbates the defection, given that the Mohring effect is now climbing up the long run curves, operating in the reverse direction. The traffic distribution changes from Q and Q' , reducing the public transport modal share vis-à-vis the private transport modal share. Not only that, the time cost of a trip perversely rises from AVC and AVC' for everyone going either by auto or bus! Indeed, the system travel time cost has increased as shown by an initial rectangle becoming yet an even larger rectangle (Fig. 7). The above phenomenon is known as the Downs–Thomson paradox (Mogridge et al., 1987; Thomson, 1977). Anthony Downs coins this result “modal convergence” as former public transport users would defect and switch to taking private transport, frustrating the congestion situation during rush hour.¹⁴

Scenario 1: Marginal Cost Pricing of Auto/Private Transport Only

We consider three scenarios that implement marginal cost pricing principles, with the first one on charging a positive price for a negative externality and the second one on charging a negative price for a positive externality. The marginal cost pricing of private transportation only—the conventional congestion pricing case—is our prime interest and forms Scenario 1 (Fig. 8). As the other alternative, public transportation, is not properly charged for, this scenario is considered a piecemeal approach to internalizing externalities. This is a realistic scenario in that public transit agencies are supposed to aim to covering their costs, despite their need for lump sum grants from governments to cover any shortfall. In recent decades there has been a call in many cities to introduce road pricing to not only tackle traffic woes but to use the collected revenue as a funding source for public transit. The condition to be met for Scenario 1 is as follows:

$$MC_A = LRAC_B (= SRAC_B)$$

By charging a congestion toll on private transportation/automobile, motorists trade off money with travel time, resulting in the time cost of a trip being lowered and the congestion toll revenues channeled into public coffers. As some motorists are priced off, they are

¹¹ After all, a transit agency would be concerned about its financial viability and firm survival rather than economic viability.

¹² Because of increasing returns nature of long-run average returns of a bus, excess capacity results.

¹³ A pre-existing gas tax for the auto mode, say, would merely shift the AVC_A curve upwards in a parallel manner.

¹⁴ The third convergence is “time convergence”. Motorists who used to travel just before or after the peak period due to congestion would move to their preferred peak time period following a road capacity increase in an urban area. Further, capacity expansion would result in the narrowing of the duration of the peak period, thereby benefiting commuters even though road capacity expansion appears to be futile diagrammatically. These urban phenomena occur because excessive congestion suppresses latent demand. It is this “triple convergence” that results in what Downs coins the fundamental law of peak-hour highway congestion.

Figure 8 Scenario 1 Marginal Cost Pricing of Auto/Private Transport Only: $MC_A = LRAC_B (= SRAC_B)$

diverted to taking the alternate public transportation mode. With a declining Long Run Average Cost for Bus, $LRAC_B$, increasing returns are reaped, with a lower travel time cost of a trip via all modes at AVC' . Because the travel time cost of a trip is lowered from AVC to AVC' , travel time savings come about for both modes. This, coupled with the travel time savings brought about by the congestion toll wedge on motorists via auto yields the shaded rotated L-shaped area of the total travel time savings. The public transport modal share goes up from Q to Q^* , strengthening its sustainability. We find that it is the correct pricing signal that brings about the genuine benefits of congestion pricing and not the raising of revenues via the collected toll revenues. Unsurprisingly, public coffer does rise by the same amount of motorists' toll payments. The trouble is that the public's trust in the government's proper handling of the revenues collected is unlikely to improve.

Scenario 2: Marginal Cost Pricing of Bus/Public Transport Only

For Scenario 2, the marginal cost pricing of public transportation only would mean that economic efficiency is enhanced for public transport via the introduction of an optimal per unit subsidy of s^* (Fig. 9). Without congestion externality from private transport being internalized, let us consider the scenario of optimally subsidizing public transport, likely to be viewed as palatable politically. Maybe considered piecemeal, it is included here for comparative purpose. The condition to be met for Scenario 2 is as follows:

$$SRAVC_A = LRMC_B)(= SRMC_B)$$

Because of the downward-sloping nature of the Long Run Average Cost of Bus, $LRAC_B$, we see that the average time cost of a trip falls for both auto and bus from AVC to AVC' , whereas the modal share for public transport increases from Q to Q^{**} (Fig. 9). By the same token, there is a further reduction of travel time for both the motorist and the bus user, with the vertical difference being $(AVC' - AVC^*)$. Considering both modes, after netting out the resource cost of the subsidy, which has to be accounted for, the rectangular shaded total travel time savings area is reduced to the cross-hatched and shaded rotated L-shaped area of the net total travel time savings depicted in Fig. 9.

Scenario 3: Marginal Cost Pricing of Both Auto/Private Transport and Bus/Public Transport

We aim to achieve first-best pricing by applying marginal cost pricing to all modes; this forms Scenario 3 as shown in Fig. 10.

$$\text{SRMC}_A = \text{LRMC}_B (= \text{SRMC}_B)$$

Figure 10 Scenario 3 Marginal Cost Pricing of Both Auto/Private Transport and Bus / Public Transport

Small (2005) argues that mass transit has failed because some view it as being the solution to our congestion problem. He models and quantifies the positive impact that road pricing has on public transport, contributing to its virtuous cycle (Small, 2004). Rather than viewing road pricing as an alternative policy to local transit provision, road pricing could be viewed as mass transit's savior and selling road pricing as a package approach to tackling gridlock.

The Role of a Transport Fund

With road pricing, our concern for compensating the affected parties—the tolled, the tolled off and tolled on—would need to be carried out in an indirect manner to ensure Pareto efficiency. One idea is to consider simply setting up a transport fund where the economic profits from heavily used roads and the diseconomies of a road network could be used to cover the economic losses from worthwhile lightly used roads as well as public transportation due to large fixed costs and the Mohring effect. Based on marginal cost pricing of all modes, we can appeal to Alfred Marshall's 'tax and bounty' system of financing:¹⁷

"One simple plan would be the levying of a tax by the community on their own incomes, or on the production of goods which obey the law of diminishing return, and devoting the tax to a bounty on the production of those goods with regard to which the law of increasing return acts sharply."

Alfred Marshall, *Principles of Economics*, 1920, Book V, Chap. XIII, Sec. 6, p. 392.

¹⁷ Marshall (1920) also observes that it is necessary to consider the cost of administering such a tax-subsidy scheme, whose electronic charging technology continues to fall and becoming more cost-effective (Hau, 2005b, 2006b).

The transport fund is a depository where the proceeds from congestion tolling are deposited and expenditures administered based strictly on the grounds of benefit-cost analysis. David Newbery (1994) shows that the replacement of current road taxes in the United Kingdom by a set of optimal road user charges would adequately cover the cost of the road infrastructure. This finding strengthens the case for establishing an independent public road authority.

Conclusions

Congestion pricing has not been successful in the past because it hurts road users on average. In fact, in the absence of compensation, most users of the transportation system area made worse off by congestion pricing. Among those who pay the toll, only a fraction of motorists who value their time very highly will feel that their time saved is worth more than the toll payment; the majority of motorists will be made worse off. Those who are tolled off clearly experience a reduction in welfare because they feel they are coerced to travel by a less desired mode, route or time of day. And those who are already on public transport may be made no better off because they are faced with more crowded buses and metros.

Without compensation to travelers, the main beneficiary of congestion pricing is the road authority that collects the tolls. With or without the establishment of a transport fund, it is only the government's *compensation* of the several groups that makes travelers themselves experience a net gain due to congestion pricing. Economic analysis suggests that, under certain conditions, compensation should take the form of:

1. road construction and improvement for those who stay on the road and pay (i.e., *the tolled*) based on an analytical framework that regards the congestion toll as a *user fee* in both the short run and the long run a la Mohring-Harwitz;
2. expanded and improved public transportation alternatives for those who are priced off and diverted from their preferred options because of the toll (i.e., for both *the tolled off* and *the tolled on*); and/or
3. lower gas taxes, purchase taxes and annual vehicle registration and license fees, etc. (for *the untolled*) if deemed excessive.

Without effective compensation schemes, congestion pricing is doomed to political failure.

Coupled with increasing concern over air and noise pollution, climate change as well as pandemics from Covid-19, the appetite for safe and socially-distanced transport—both private and public—will rise. The trend of working from home may offset the demand for face-to-face interaction in the workplace but not necessarily reduce the demand for socially-distanced automobile travel to nonwork destinations. It is incumbent that the first-best pricing strategy espoused here, or road pricing in common parlance rather, be pursued and externalities charged for. Based on a combined assessment of the conceptual underpinnings and international experiences (see Case Study below), congestion pricing offers a way out of our present gridlock, both trafficked and political.

A Practicable Proposal for the Implementation of Electronic Road Pricing in Hong Kong

The previous three articles have developed the theory of marginal cost or congestion pricing for roads and the implications for an efficient urban transportation system covering both private and public transportation. The article discusses the possibility of electronic road pricing, the history of its development in various cities across the world and the practical difficulties of applying it in one city, Hong Kong.

Technological breakthroughs in computers, radio frequency identification, global positioning systems, intelligent vehicle transportation system, and smart transportation have made automatic vehicle charging become a reality. The earliest proponents of Electronic Road Pricing (ERP) are Nobel Laureate [Vickrey \(1960\)](#) and panel members of the UK [Ministry of Transport \(1964\)](#), authors of the famous Smeed Report, both of which formed the precursors of Hong Kong's pioneering ERP feasibility study.

Hong Kong was the first city worldwide to undertake actual technical feasibility of ERP from 1983 to 1985 ([Transpotech, 1985](#)). Despite being tested and having attained over 99% effectiveness and reliability, the soldering of a video-cassette-sized electronic number plate on the underside of a private car—thus revealing a vehicle's whereabouts—helped spell its political demise. One lesson to be learnt from that thorough study was that the singling out of the private car motorist as the sole group to be charged ERP would doubly increase the burden and raise the ire of the private car motorist. The study also suggests that granting vehicular exemptions to certain vehicle types or groups would be a slippery slope. Viewed as “just another tax,” the promise of lowering annual vehicular license fees to offset ERP at the eleventh hour failed to assuage opponents of ERP. Nevertheless, the annualized benefit-ratio of implementing a pilot stage of ERP in Hong Kong is impressive, ranging from 14.7:1 to 17.8:1 ([Hau, 1990](#)).

With further technical advancements, the second feasibility study of ERP in Hong Kong from 1997 to 2001 reported significant time savings and vehicle operating cost savings and overcame privacy concerns by appealing to the use of Dedicated Short-range Radio Communication (DSRC) system ([Transport Department, 2001](#)). The report broaches the concept of revenue neutrality by proposing that the ERP gross revenue proceeds of HK\$0.4 to HK\$1.3 billion every year be ploughed back for transport infrastructure investment.

Meanwhile, in 1998, Singapore turned its paper-based road pricing system—the so-called Area Licensing Scheme, which had first begun in June 1975—into the world's pioneering ERP system. Using DSRC and smart card technology, Singapore adopted a flexible, cordon-based system in the charged area and imposed ERP rates according to vehicular size and type. The simplicity and beauty of setting a target speed range of 20–30 km/h on major roads in the cordoned charging area and 45–65 km/h on expressways for all to see and monitor has much to commend for, as opposed to appealing to the standard approach of calculating traffic volumes, volume–capacity ratios, service levels, road capacities, and so on.

Soon afterwards, on February 17, 2003, London defied informed critics by fast-tracking congestion charging with its Automatic Number Plate Recognition (ANPR) system, resulting in a costlier system which still yielded positive net benefits ([Santos et al., 2006](#)). London Mayor Ken Livingstone came up with important complementary measures such as using the congestion charging revenues to finance an expanded public transport fleet. London's resounding success with its opening of £5 congestion toll during daylight hours also put paid to skeptics' doubts on the feasibility of implementing road pricing in a major world city where the electorate holds sway.

Following that, Stockholm introduced a congestion charge for a 7-month trial period from January to July 2006. The concern of reverting to precharge congested traffic conditions, Stockholm city residents' preference for a better environment and air quality and the provision of ERP revenues for new road construction all contributed to the positive outcome of a referendum that made congestion charging in Stockholm permanent from August 2007 onwards to date ([Eliasson, 2009](#); [Simeonova et al., 2018](#)).

Other notable examples of the successful implementation of ERP include Milan, Italy in 2001, Durham, England in 2002, Valetta, Malta in 2007 (a one-of-a-kind, time-based system) and Gothenburg, Sweden in 2013. In recent years, a flurry of congestion charging systems has started, with the three historical Norwegian toll rings' flat tolling progressing to time-differentiated charging, together with several new toll rings being variable-tolled: Trondheim in 2012, Kristiansand in September 2013, Bergen in February 2016, Oslo in October 2017 (which has three cordons: city border, original cordon, and inner cordon), Nord-Jren in March 2019. To tackle both chronic traffic congestion and help finance its public transit system, a congestion pricing proposal to charge vehicles entering Manhattan south of 60th street in New York City in 2022 passed the New York State Budget in April 2019 but stalled at the federal level.

For most of the aforementioned ongoing congestion charging schemes worldwide, the net revenues are used for public transport infrastructure, services and improvements, road investments, busways, air pollution-reducing policies, and/or transport safety enhancements. A major finding of the British and Scandinavian road pricing desk studies and operational schemes is that motorists are against having to pay more than they already have but when the collected road pricing revenues are recycled for road construction and improvement and/or better public transport provision, there is a turnaround in support of road pricing as a package approach (Gu et al., 2018; Jones, 1991).

It is therefore right and prescient for the Financial Secretary Paul Chan Mo-po to promulgate – in a groundbreaking paragraph for transport in Hong Kong—in his annual Budget Speech 2019–20 on February 27, 2019: “Electronic road pricing does not aim to increase government revenue” and that Government will provide equivalent net revenues generated from a proposed ERP Pilot Scheme “for implementing measures to improve public transport services and encourage wider usage.” In April 2019, the Transport Department of the HKSAR Government initiated “Smart Mobility—Intelligent Traffic Management: Electronic Road Pricing Pilot Scheme in Central Core District: Concepts and Preliminary Ideas” (Transport Department, 2019).

Despite the high first registration taxes and annual license fees that rank amongst the highest in the world, travel demand still far outpaces society’s ability to provide sufficient transport infrastructure, resulting in traffic speeds in Central District that are a little faster than a slow jog. In order to fully exploit the benefits of the enhanced capacity provided by the recent opening of the HK\$36 billion Central Wan Chai Bypass in February 2019, ensuring the Bypass’s efficient use is of high priority. If road pricing is continually forestalled, suppressed travel demand long held back by traffic congestion itself would more sooner than not be released—due to the fundamental law of traffic congestion and traffic paradoxes—that would swamp the Bypass’s carrying capacity.

The promise to earmark the net revenues from the ERP Pilot Scheme to improve public transport services satisfies the *sine qua non* for ERP’s successful implementation in several overseas experiences mentioned above. It appears that Hong Kong needs to move one step further and redistribute the revenues in a way that directly benefits the public transport passengers by placing a part—such as a half—of the collected revenues in passengers’ pockets. As Central is the location where the charging zone is situated, a simple proposal—call this the flat rate subsidy proposal—is that a fixed amount be compensated for a public transport user whose destination is Central. Alternatively, a variant—call this the proportionate subsidy proposal—is that a certain percentage of a user’s public transport fare whose destination is Central be compensated. (The subsidy could be set conservatively to ensure ERP revenue neutrality.) What is the conceptual basis for such a compensation proposal?¹

1. The proportionate subsidy proposal is consistent with the *first-best pricing principle* for public transport (including both bus and rail) to be subsidized on the basis of both the increasing returns to scale due to its large fixed cost and the Mohring effect.
2. The subsidy proposal—be it flat rate or proportionate—is *progressive*.
3. Both subsidy proposals have a *lower relative price for public transport* as they lower the public transport fare for users whose destination is Central relative to private car use, so that travel demand using scarce road space is in the right direction with more public transport use and less private car use being incentivized, helping to further strengthen the alleviation of Central’s traffic bottlenecks.
4. Both subsidy proposals possess a *marginal economic incentive* that tilts travel mode choice from a less environmentally friendly mode to a more developmentally sustainable one.
5. Both subsidy proposals are along the lines of Nobel Laureate Richard Thaler’s *nudge theory* in behavioral economics in which the subsidy serves as the nudge—a negative surcharge—tilting the use of mode choice towards public transport and away from private car use.
6. Both subsidy proposals follow the *user pays principle*—just as the proposed charging of private car use does—by subsidizing a “good” (public transport use) and taxing (or, more accurately, pricing) a “bad” (private car use entering the CBD) and are fully consistent with the *polluter pays principle* behind Hong Kong’s soon-to-be-implemented mandatory waste charging scheme.
7. Both subsidy proposals—in conjunction with the proposed charging of private car use – would help forestall the Central Wan Chai Bypass from being overcome within a few years’ time due to latent demand *a la* Downs’s law. In October 2005, the Harbor-front Enhancement Committee’s “The Final Report of the Expert Panel on Sustainable Transport Planning and the Central—Wan Chai Bypass (CWB)” urges that ERP be pursued once CWB comes into being as the Bypass would serve as a viable escape route for the through traffic that avoids the charging zone completely.
8. To minimize administrative costs, it is proposed that the compensation scheme be piggybacked onto the innovative Public Transport Fare Subsidy Scheme (PTFS) already in place since January 2019 using the ubiquitous Octopus reusable contactless smart stored value card universally held by Hong Kongese. (In January 2020, the enhanced PTFS Scheme has an increased monthly subsidy cap of HK\$300, a subsidy rate of 33% in excess of HK\$400 in monthly public transport expenditures incurred by a user on franchised transport modes.²) By piggybacking onto the Transport Department’s hugely popular Subsidy Scheme, the compensation proposal benefits from the same properties as its PTFS scheme which has the side effect of *stimulating intermodal competition* by transit riders voting with their feet and revealing their preference for that public transport mode that yields the best combination of service performance and affordability. It is through increased intermodal competition that the traveling public’s well-being is served and even enhanced rather than via tightened regulatory rules (aimed at, for instance, the Mass Transit Railway Corporation), which may not be as responsive and effective whenever the market suddenly turns.

¹ The proposal is backed up by a group of 25 transportation researchers having Hong Kong’s long term well-being at heart. The group made up most of Hong Kong’s transportation experts.

² From July to December 2020, the HKSAR Government further lowered the monthly deductible by half to HK\$200 (from HK\$400) to participate in the PTFS Scheme because of the COVID-19 pandemic.

In 2006, the Government's Council for Sustainable Development released the results of a large-scale survey on "Clean Air and Blue Skies—the Choice is Ours" indicating that the majority of the survey respondents expressed support for a better environment via road pricing. The survey results are consistent with the well-known fact that over nine-tenths of trips made during peak-hour traffic are by public transport and only one-tenth is by private car.

The political difficulties of congestion pricing in the case of Hong Kong are not insurmountable if the proceeds of congestion pricing are made tangible and shared by all affected parties in the transport community: the tolled, the tolled off, and the tolled on. It is envisaged that road pricing implementation in major metropolises will hopefully arrive sooner rather than later.

Introduction

Transport systems are the veins of the local, national, and global economy. Intelligent Transport Systems (ITS) aims to exploit information and communication technologies for efficient and safe mobility of people and goods. Advanced Traveler Information System (ATIS) is an important component of ITS, where the aim is to provide accurate and reliable information to the traveler for their travel over the network.

The information of interest to the traveler includes, not limited to, pretrip multimodal trip planning and route choice options, on route dynamic expected arrival time, traffic incidents, roadworks, hazards, and infrastructure restrictions. Generation of such information requires significant amount of monitoring data from the transport systems, which is primarily acquired and managed by public sector (transport agencies). Over the last decade, private sector has increasing business interest towards acquiring and storing road traffic conditions. The breadth of the information needed by different traveler and travel purpose requires multiple means to disseminate the information.

Need for Traveler Information

A significant amount of our precious time is wasted on non-optimized travel. Multiple reports have been published highlighting the “extra time” lost due to uncertainties in travel. Recently, TomTom (https://www.tomtom.com/en_gb/traffic-index/) has reported on average extra time spend in traffic 2019 was 87 min. The uncertainties in the travel leads to travel stress, aggressiveness, and road rage. Researchers have shown that an aggressive and stressed driver is more likely to have risky driving and lead to a crash (Bowen et al., 2020; Öz et al., 2010). Availability of real time and predictive traveler information should reduce traveler stress and related detrimental impacts.

Information Generation

Transport agencies collect significant amount of road network monitoring and related data through traditional loop detector, floating car data, manual survey, and traffic surveillance camera. With advancement in technology, new data sources such as Bluetooth and Wifi based MAC scanners (Advani et al., 2019; Bhaskar and Chung, 2013), GPS (Byon et al., 2006), and emerging drones (Barmounakis and Geroliminis, 2020; Kamnik et al., 2020) are being exploited for spatial temporal traffic monitoring. Private firms such as Google (<https://www.google.com/maps>), Waze (<https://www.waze.com/>), Here (<https://www.here.com/>), Intellematics (<https://www.intelematics.com/>), and INRIX (<https://inrix.com/>) are also collecting traffic congestion data on the network and these data is available (at cost) to the transport agencies. It is worth mentioning that the availability of the data from multiple sources can lead to over information. There is a need to fused data from multiple sources for a single point of truth. The fusion algorithm should consider the confidence and reliability of individual data source.

In addition to traffic congestion, information on road works, traffic crashes, hazards, flash flooding, fire, weather, etc. is also collected and integrated with the traffic conditions. Recently, there is increasing focus of the government agencies to open the data, and different initiatives are taken for real time sharing of the data through open data portals. The availability of such data provides opportunities to the independent developers to develop tools for traveler information.

Information Dissemination

After decades of development, ATIS is now capable of providing numerous kinds of information, covering almost all aspects of travel such as trip planning, route navigation, and real-time traffic conditions (Ben-Elia and Avineri, 2015; Chorus et al., 2006; Gössling, 2018). The focus, however, is usually quite narrow, targeting on either route choice (Bagloee et al., 2014; Ben-Elia and

Avineri, 2015; Liao and Chen, 2015), route/path switching behavior (Guo, 2011; Lou et al., 2017), mode and departure time choice (Gan and Ye, 2015) or activity planning (Liu, 2001).

The information supplied through various ATIS sources can be classified into three groups according to their function and needs: knowledge, risk reduction and efficiency. The provision of ATIS is used to gather knowledge of specific types of information (route guidance, descriptive information, etc.) and is delivered through various media sources (internet, text-messages, Variable Message Signs, etc.). The knowledge is applied in specific types of choices (departure time, route, or mode, etc.), made under different contexts (habitual trips, business trips, recreational trips, etc.) in various travel situations (pre- or in-trip, normal or accident conditions, etc.) to improve the overall efficiency of the trip.

For personal vehicle drivers, the provide information updates drivers on current roadway conditions—including delays, incidents, weather-related messages, travel times, emergency alerts, and alternate routes. It can be offered with value added options like sports scores, stock quotes, yellow pages, and current news. The ATIS is useful for various activities in pretrip, on-trip and posttrip phase as well as for all modes of travel including a private, public transport, or a multimodal traveler.

The pretrip travel information allows travelers to access real time inter modal transport information at home, work, and other major sites where the trip originates. Advanced pretrip traveler information system devices focus on providing real-time traffic information but often bundle it with transport and traveler services information. However, ATIS information is prominently used in during the trip to have a knowledge about traffic conditions, incidents, construction, transit schedules, and other mode choice options to drivers of personal, commercial, and public transit vehicles. For example, in case of using public transport, choosing an optimized itinerary requires knowledge about public transport network and services. On top of these, multi-modal trips, which involve multiple modes (e.g., plane, train, taxi) and highly probably various transport operators, are even more demanding.

The essentiality of the information in various modes and phases can be categorized as:

Multimodal trip planning: The ATIS information assists traveler during pre- and on-trip phase to find multimodal trip options/paths to reach their destination. Moreover, during nonrecurrent conditions, the on-trip planning computes and proposed alternate paths to reach the destination.

Route guidance service systems: The provided information helps traveler navigate throughout their trips for providing directions (drivers/pedestrians) or public transport navigation guidance (for passengers).

Advisory information: The advisory services includes information such as parking details, incident/congestion/ delay warning, weather information, public transport service schedule, traffic information, and other trip related information.

The disseminated information to drivers before and during trips allows them to make more effective travel decisions about changing routes, modes, departure times, or even destinations. The information also helps the travelers with planning, perception, analysis, and decision-making of their trip to improve convenience, safety, and efficiency of travel (Adler and Blue, 1998; Dong et al., 2010; Kumar et al., 2003).

Thus, the aim of the ATIS is to automatize the entire process of searching for relevant and useful resources (e.g., existing ATIS's, information sources, services) available on the Web, accessing them, and combining acquired information and services to build travel solutions tailored to each traveler's requests and needs.

Traveler information is delivered through various means which includes:

1. Television and radio channels: The information provided here is generally "near" real time travel conditions on the road with focus on major delays due to incidents.
2. Roadside variable message signs (VMS): The variable message signs are strategically placed along the major corridors to disseminate real time expected travel time along the corridor. For instance, on motorways the travel information can be to different exits. The VMS are also used to warn drivers of major incidents or hazards on the road.
3. Websites and apps related to route guidance and trip planning: These sources primarily focus on the route guidance and multimodal trip planning, and if connected to the network can provide dynamic updates during the travel. The information can be more personalized, where traveler has options to optimize the trip based on destination, departure time, and infrastructure usage (such as avoid toll roads). Google Maps, Waze, QldTraffic (<https://qldtraffic.qld.gov.au/>) are few examples of real time traveler information.
4. In vehicle time navigation systems, such as vehicle information and communication systems in Japan (<https://www.vics.or.jp/en/know/index.html>) and TomTom (tomtom.com).

Recent Trends in ATIS

The recent applications of ATIS are in vehicle routing and navigation systems that keep drivers informed about the traffic, vehicle, roadside condition all together in a single service. When integrated with an advanced traffic management system, information on recurrent traffic congestion can be obtained. This helps to select and display optimum routes based on real-time traffic data such as the distance/time/cost to the destination, and notification of incidents (route information navigation) can be provided. The integrated service is usually used for the in-vehicle guidance system for the recent applications.

The in-vehicle motorist services information provides motorists with commercial logos and signing for motel, eating facilities, service stations, and other signing displayed inside the vehicle to direct motorists to recreational areas, historical sites, etc.

In-vehicle signing information provide noncommercial routing, warning, regulatory, and advisory information inside the vehicle that are permanently available on the roadway.

In-vehicle safety advisory and warning systems provide warnings of unsafe conditions and situations on the vehicle/roadway ahead that could affect the driver.

The massive availability of data and services, resulted from expansion and use of internet opens a new perspective towards the design of ATIS that exploits large, dynamic, and open set of data sources as well as services coupled with advancement in artificial intelligence. Currently, numerous ATIS's are in operation. However, most, if not all, ATIS's are designed to target only certain types of travelers, travel modes, transport services provided by certain operators, and/or geographical coverage. Therefore, regardless of the significant number of existing ATIS's, travelers are quite often still required to consult multiple ATIS's and/or to seek for travel information from various sources to acquire enough information and assistance for their trips.

Though the systems possess several advantages, it faces budgeting and funding challenges. However, the same infrastructure that provides traveler information also enables more effective incident management and performance measurement—which can mean a greater return on the investment. Maintaining and upgrading these systems to reflect the most up-to-date technology requires implementation and maintenance funding. Another issue with the ATIS system usage is the safety concern by using system while driving and proper use of publicly collected traffic information when distributed by private interests. Moreover, issues are being faced in liability for distributed information that is either false, inaccurate, or unreliable and may be blamed for damage of some kind.

Introduction

Travel time, a fundamental measure in transportation, can be defined as the time taken to traverse a route between any two points of interest. Urban travel times are prone to higher degrees of variability due to the presence of traffic influencing events (traffic incidents, work zone activities, and weather), traffic demand (fluctuations in demand, special events, etc.), and presence of physical features (traffic control devices, inadequate base capacity). Due to this variability, travel times for a similar trip during different hours of a day or over the days become inconsistent. In order to capture these inconsistencies, researchers have defined several measures. Travel Time Reliability (TTR) and travel time variability, which are related, but different in their focus, are most commonly used to describe these inconsistencies. Based on literature, variability can be expressed as inconsistency in operating conditions (Lomax et al., 2003). On the other hand, TTR is defined as the consistency or dependency in travel times as measured from day to day and/or across different times in a day. In other words, it can be defined as a measure of the dispersion (or spread) of the travel time distribution (Federal Highway Administration, 2017).

While both of these measures are important, variability is related more to the facility and therefore more pertinent to transportation agencies (Lomax et al., 2003). Reliability is more pertinent to travelers since it is related to their travel experience and is significant to many transportation system users such as vehicle drivers, transit passengers, freight shippers, etc. For example, travelers and shippers want to know when they need to leave, or when the truck has to depart, in order to make an on-time arrival. Both user groups may also want to know which paths they should use to minimize the probability of unforeseen delays. Managing agencies/operators want to know where the problem spots lie; where the network segments are that make the travel times vary. If the transportation system was 100% reliable, with the same travel times all the time, none of this would be an issue.

Traffic engineers started recognizing the importance of travel time reliability as it better quantifies the benefits of traffic management and operation activities than simple averages. The initial research on reliability was mainly of qualitative in nature, mostly questionnaires ascertaining travelers' preferences with respect to the quality of their commute (Vaziri & Lam, 1983; Chang & Stopher, 1981; Prashker, 1979). However, advances in traffic data collection techniques generated huge amount of data in both real-time and historic contexts, which were used to quantify the reliability and various performance measures were reported. These are discussed in the next section.

Reliability Performance Measures

Travel time reliability measures the performance of an urban arterial. In a broader sense, reliability is an attribute of mobility and congestion. Traditionally, the dimensions of congestion are spatial (how much of the system is congested?), temporal (how long does the system got affected?), and severity-related (how much delay is there or how low are travel speeds?). Reliability adds a fourth dimension: How does congestion change from day to day? (SHRP Report, 2014). From a measurement perspective, reliability is quantified from the distribution of travel times, for any given section/network that occurs over a significant amount of time.

Classification of Measures

The travel time reliability measures can be broadly categorized as below (Lomax et al., 2003; Van Lint et al., 2008).

Table 1 Statistical range measures

Measure	Definition	Formulae
Standard Deviation	Deviation of travel times from the average travel time.	$\sqrt{\frac{(x_i - \mu)^2}{N}}$
Travel Time Window	Variation of travel time around the average expressed in a “plus-minus” form.	$Average\ Travel\ Time \pm Standard\ D$
Percent Variation	Variation of travel time around the average expressed in ratio	$\frac{Standard\ Deviation}{Average\ travel\ time} * 100$
Width (τ^{var})	Measure for width of the travel time distribution	$\tau^{var} = \frac{T90 - T10}{T50}$
Skew (τ^{skew})	Measure for skew of the travel time distribution	$\tau^{skew} = \frac{T90 - T50}{T50 - T10}$
Unreliability index (UI_r)	Measure for combination of width and skew of the travel time distribution	$UI_r = \tau^{var} \ln \left(\frac{\tau^{skew}}{L_r} \right), \text{ for } \tau^{skew} > 1 \frac{\tau^{var}}{L_r}, \text{ otherwise}$
Variability index	Ratio of the peak to off-peak variation in travel conditions	$\frac{(Upper\ 95\% - Lower\ 95\%)_{peak}}{(Upper\ 95\% - Lower\ 95\%)_{off-peak}}$

x_i is i^{th} travel time observation; μ is the average travel time, N is total number of observations; $T90$, $T50$, $T10$ are the 90th, 50th and 10th percentile travel time respectively, L_r is route length
 Note: For all the above discussed measures, higher the value of the measure, higher the unreliable condition

- Statistical range measures
- Buffer time measures
- Tardy trip measures
- Probabilistic measures
- Congestion/volume-based measures

The statistical range measures analyses travel time variability based on historical data or real-time information, while the buffer time type indicates the extra time to be allotted for a trip over the average conditions to combat the uncertainty in travel conditions. The tardy trip measures indicate unreliable conditions from the perspective of the worst trips or the unlucky travelers. Probabilistic reliability measures mainly reflect the probability that the travel time can match the specified conditions or thresholds in the form of probability distribution. Congestion/Volume-based measures represents unreliable condition in terms of congestion observed. These measures are discussed in detail below.

Statistical Range Measures

These measures generally use standard deviation or spread of the distribution to represent the travel conditions that are experienced by travelers (Lomax et al., 2003). These are often represented as a plus/minus times the standard deviation from the mean value. Measures that fall into this category include standard deviation, percent variation (coefficient of variation), travel time window, etc. Measures that fall into this category are briefly discussed in Table 1 (Lomax et al., 2003; Van Lint et al., 2008).

It has to be noted that standard deviation type of expression indicates the spread of travel time around some expected value, that is, average travel time, implicitly assuming travel times to be distributed symmetrically. For example, in case of normally distributed travel times, using a window of one standard deviation will encompass 68% of the days or peak periods or whatever time period is chosen for analysis. Analysis conducted by Van Lint and Van Zuylen (2005) showed that a symmetrical distribution can probably occur only under free flow conditions. Van Lint et al. (2008) proposed skew (τ^{skew}), width (τ^{var}) and a combination of skew and width (UI_r), that can indicate the likeliness of incurring a very bad travel time (large values for unreliable period and small otherwise) as robust indicator of reliability.

Buffer Measures

Buffer measures typically provide the extra time that travelers need to allot to their trip due to travel time variability, in order to make an on-time arrival to their destination. This extra time or “buffer” reflects the uncertainty in travel conditions. Measures in this category include buffer time, buffer time index (BTI), planning time and planning time index (PTI). Table 2 summarizes the existing buffer measures (Lomax et al., 2003; FHWA, 2017).

Previous studies showed similar trends from all of the above measures, with the planning time index as slightly exaggerated and buffer index as the most conservative (Lyman and Bertini, 2008). A study by Florida DOT (SIS Final Report, 2010) reported that buffer index could be an unstable indicator of changes in reliability as it can move in a direction opposite to the mean and percentile-based measures. This is mainly because buffer index uses both the 95th percentile and the mean travel time, and the percent change in these values can be different from time to time. If one changes more in relation to the other, counterintuitive results can appear. Fan and Gong (2017) used travel time reliability measures such as frequency of congestion (FOC) and PTI to identify and rank recurrent freeway bottlenecks and their results indicated that both FOC and PTI are capable of identifying and ranking bottlenecks.

Table 2 Buffer measures

Measure	Definition	Formulae
Buffer Time	Extra time that is allotted to ensure on-time arrival. This includes unexpected delays.	$T95 - \text{Average travel time}$
Buffer Time Index	Extra time that is allotted to ensure on-time arrival expressed in terms of percentage of the average travel time. This includes unexpected delays.	$\frac{T95 - \text{Average travel time}}{\text{Average travel time}}$
Planning Time	Total time that travelers should allocate towards their trip to ensure on time arrival. This includes buffer time as well.	$T95$
Planning Time Index	The planning time index compares near-worst case travel time to a travel time in light or free-flow traffic. -flow travel time. This Includes typical delay as well as unexpected delays	$\frac{T95}{\text{Free flow travel time}}$

T95 is the 95th percentile travel time

Note: For all the above discussed measures, higher the value of the measure, higher the unreliable condition

Table 3 Tardy trip measures

Measure	Definition	Formulae
On-time Arrival	Employs a threshold travel time to the trips to determine the percentage of trip that can be termed reliable. The higher value of the measure indicates good reliability.	$100 - (\% \text{ of trips greater than } 110\% \text{ of avg. TT})$ where, TT stands for Travel Time
Misery index	Measure that indicates how much time the worst trips exceeded the average travel time, expressed in percentage of the average travel time. Higher value indicates, greater unreliable conditions.	$\frac{\text{Avg. TT of longest 20\% of trips} - \text{Avg. TT}}{\text{Avg. TT}}$

Tardy Trip Measures

Tardy trip measures use the number of late trips to measure system unreliability. Key measures in this category are on-time arrival and misery index. **Table 3** explains the tardy trip measures in brief (Lomax et al. 2003).

Lomax et al. (2003) reported two issues related to the threshold value concept (1) threshold value for late arrival for all trips may not vary linearly and (2) it is not only related to trip duration but also to the previous and next activity. Also, they reported that “Being late may be more acceptable if the traveler is coming from an important activity and it may be less acceptable if they are going for an important activity.” Hence, more testing of the acceptable lateness concept needs to be done. Misery Index (MI) can evaluate the negative attribute of trip reliability and it can be judged by how much the average travel times of the unluckiest trips (20% of the worst trips in an hour or day) exceeded the mean travel time (Lomax et al., 2003). It provides an idea on how bad the worst trips are and to what extent of extreme travel times the travelers are exposed to.

Probabilistic Measures

In this category, travel time reliability is expressed as a probabilistic measure. Probabilistic travel measures often use a threshold travel time or a predefined window to differentiate between reliable and unreliable travel times (Van Lint et al., 2008). Asakura (1996) proposed a trip to be reliable if the probability of the trip between a given OD pair to be completed within a specified interval of time is high. The Dutch Ministry of Transport, Public Works and Water Management proposed a reliability measure which stated that all trips should be made within 20% bounds of median travel time (Verker and Waterstaat, 2004). **Table 4** shows probabilistic measures used for quantifying reliability (van Lint et al., 2008). Along with these two measures, concepts of cumulative curves can be used to assess the reliability by plotting travel times in x-axis and cumulative probability on y-axis.

Table 4 Probabilistic measures

Measure	Definition	Formulae
Pr(α)	Determines probability that travel times occur larger than multiple of some predefined travel time threshold. Higher value indicates greater unreliable condition	$Pr(\alpha) = P(TT_i > \alpha * TT_{50})$, e.g. $\alpha = 1.2$, where TT_{50} is the 50th percentile travel time A use of 1.2 as α refers to the probability that travel time is larger than the median travel time + 20 %
AVV 2004 Probabilistic Measures	Determines if at least 95% of all travel times does not deviate more than 10 min from the median travel time for short routes, while for longer routes, if 95% of the travel times are within a 20% margin around the median.	$Pr(TT_i \leq 10 \text{ mins} + TT_{50}) > 95\%$, for routes < 50 km $Pr(TT_i \leq 1.2 \text{ mins} + TT_{50}) > 65\%$ for routes > 50 km

Congestion Based Measures

Volume, speed, and congestion frequency graphs are reported to depict reliability (Lomax et al., 2003). These measures help to view the variability in traffic condition and determine the unreliable periods or days. Frequency of congestion (FOC) is a well-known reliability measure used in many studies to report reliability (FHWA, 2017; Fan & Gong, 2017). FOC is defined as the percent of days or time or trips during which the travel times exceed some threshold value. The threshold value can be chosen at the discretion of the analyst. Higher values of FOC indicate unreliable conditions. FOC is relatively easy to compute if continuous traffic data is available (FHWA, 2017). Each of these measures quantify the reliability in terms of certain selected variables and got advantages and limitations. Next section discusses a case study where these measures are calculated and analyzed for their performance.

Case Study

To better understand and depict the applicability of the reliability measures, a case study is carried out by collecting data from a 1.6 km urban arterial connecting the Bharathi Nagar and Vijaya Nagar intersection, located at southern part of the Chennai city as shown in Figure 1.

The data for the proposed analysis has been collected for a period of 1 month using Global Positioning System (GPS) fitted buses that are plying in the study corridor. The raw GPS data provided information about the position (latitude and longitude) of the bus at every 5 sec interval, which can be further processed to obtain travel times. For examining the variations of reliability along the study corridor, the 1.6 km corridor was segmented into eight subsections of 200 m length and the time taken to cover each subsection was calculated using linear interpolation technique. The travel time data thus generated is further used to generate reliability metrics.

Traffic in any roadway is expected to follow certain temporal and spatial patterns. Temporal patterns can include within day variation (peak and off-peak) and day-to-day variations (weekday vs weekend or day of the week variation), whereas spatial patterns may be specific to certain sections or adjacent sections. To understand these influences on travel time, the data collected from the study corridor was analyzed. To start with, the spatial analysis was done to identify the variation in travel time across various segments in the study corridor. Figure 2A is a sample plot showing travel time variation over various sections.

From Figure 2A, it can be observed that there exists a strong segment specific pattern in travel time. For example, section 7 shows higher central value and spread in travel times compared to other sections. Hence, it was decided to analyze each section separately. In the next level, analysis was conducted to identify the variations in travel time across days as shown in Figure 2B for a sample section. From Figure 2B, it can be observed that travel times observed across various days of the week does not show much difference. Both central values and spread are in similar range. This was observed to be true for all other sections as well. Hence, it was decided to consider the travel time data from all days together while calculating the reliability metrics. Similarly, within day variation, that is, hourly box plots are plotted for each section separately and a sample hourly box plot for a day is shown in Figure 2C. From Figure 2C, it can be observed that there are significant hourly variations over the day. This was observed to be true for all other sections for all days and hence, every hour is analyzed separately to capture the temporal variations.

Thus, based on the above observations, reliability metrics are calculated for each section and each hour separately after clubbing the travel time data of all days together to analyze the spatial and temporal reliability variations. Further, outliers are removed using median absolute deviation technique (Leys et al., 2013) before calculating the reliability measures. Reliability measures under each group (statistical, buffer, tardy trip, probabilistic, and congestion measures) calculated and related discussions are presented in the next section.

1. *Statistical range measures* All measures that are presented in Table 1 are calculated and the applicability of these measures is discussed. Figure 3 to Figure 9 show different statistical range reliability measures calculated using the data. In these figures, a continuous color coding is used to visually demonstrate reliability scenario along with the numbers. Under this color coding, green refer to very good reliability, yellow represent moderate reliability, and red a very poor reliability condition. From Figure 3

Figure 5 Percent variation (expressed as percentage).

to Figure 6, it can be observed that (1) section 7 and 8 show poor reliability in almost all time periods and section 6 shows relatively poor reliability in the evening peak hours and (2) starting sections 2, 3 are more vulnerable in the afternoon peak hours. All these agree with the field condition observed. Although, these measures are able to represent field scenario, they suffer from (1) the assumption of symmetrical travel time distribution and (2) giving equal weight age to late and early arrivals, while travelers are concerned more about late arrivals. From Figure 7 to Figure 9, it can be observed that variability index, skew and unreliability index were not able to represent field condition. Data was analyzed further to understand this and it was observed that the left hand side of the distribution (T50-T10) is more steeper than the right hand side of the distribution (T90-T50), resulting in high value of skew. This means, skew only identifies a period as unreliable when the distribution is highly left-skewed, which occurs mostly during congestion onset or offset, that is, when the distribution is highly skewed. Thus, skew may be able to capture the congestion onset/offset better, but may not capture reliability during regular peak hours. A similar contradictory observation can be seen from Figure 9 as well indicating section 6 to be more unreliable than section 7 and 8. It may be

Figure 9 Variability index (expressed as ratio).

because variability index captures only the difference between upper and lower 95% confidence value, but ignores the absolute value of the travel times. Overall, though unreliability index, variability index and skew were able to depict the reality to some extent, they are highly affected by the distribution of the collected data, that is, these measures were either penalized by the travel times in left hand side of the median (underestimating the unreliability) or right hand side of the median (overestimating the unreliability). On the other hand, though other metrics were able to completely depict the reality, they completely depend on spread of travel time around some expected travel time value and such information can only be an abstract indicator for the travelers.

Figure 13 Planning time index (expressed in ratio).

2. *Buffer measures* Figure 10 to Figure 13 show different buffer reliability measures calculated for the data under consideration, where the reliability status is indicated by the previously used color coding. Here, buffer time considers only unexpected delays and planning time considers both unexpected and typical delays. From Figure 10 to Figure 13, it can be observed that all buffer time measures were able to depict the field condition to a great extent. However, it has to be noted that: (1) buffer time index has to be cautiously used because of the unstable indication of changes in reliability as it can move in a direction opposite to the mean and percentile-based measures (SIS Final Report, 2010) and (2) planning time index, that shows exaggerated trends when compared to buffer time index and planning time (Lyman and Bertini, 2008). For example, from Figure 13, it can be observed that at time slot 7–8 pm, planning time (Figure 12) for section 6 is 224.33 secs and section 7 is 226.28 secs and corresponding

Figure 16 $Pr(\alpha)$.

planning time index (Figure 13) are 14.02 and 10.29 secs, respectively. Planning time at this period differs by only 0.87% between the sections whereas planning time index differs by almost 40%. This shows that even though the 95th percentile travel times are almost equal, section 6 is more unreliable at this period. This may be because of the presence of wide variation across a free flow travel and a worst case travel in section 6 compared to section 7. This aspect can be captured by the planning time index. Another benefit of this measure, is that it can be directly compared against travel time index on similar numeric scales, which is a measure of average congestion (Lomax et al. 2003). Overall, these measures connect to the way decisions are made by the travelers. The effect of uncertainty on decision-making can be more related by these measures as it evaluate the real traffic conditions against average condition. However, measures like buffer time index has to be cautiously used because of the unstable indication of changes in reliability over time.

3. *Tardy trip measures* Figure 14 and Figure 15 show different tardy trip measures calculated for the current data, where the reliability status is indicated by the same color coding. Figure 14 shows the percent of trips that lies within an acceptable lateness threshold. From Figure 14, it can be observed that a few time periods for some sections are highly unreliable due to relatively wide spread of travel time (between average and 110% of average travel time). However, the reliability metric is not consistent with the field congestion as well as other measures. This may be because on-time arrival considers only average and average+110% travel times whereas measures like planning time index considers the variability between free flow and near maximum travel time. Upon detailed investigation, it was also observed that the reliable periods indicated by on-time arrival measure shows worse travel times than the unreliable ones. For instance, at 8 pm, section 6 (marked as unreliable by on-time arrival) experience an average travel time of 131.74 secs whereas section 7 (marked as reliable by on-time arrival) experienced about 184.01 secs. This congestion condition could not be captured by the on-time arrival which may possibly due to the choice of the threshold value. On the other hand, the Misery Index that evaluates the negative attributes of trip reliability (how much the average travel times of the unluckiest trips exceeded the mean travel time) shows that section 7 and 8 has poor reliability in most of the time periods and

Figure 18 Hourly cumulative probability plot for section 6.

section 6 is critical during evening peak hours. The results are consistent with results from buffer measures and field scenario. Typically, this measure is useful for planning agencies and traffic analysts to identify critical areas and time periods. Overall, based on the metrics calculated using tardy trip measures, it can be observed that misery index was able to depict the field condition to a great extent and it has been recommended as a good measure of reliability (Lomax et al., 2003). However, the other tardy trip measure, “on-time arrival” could not depict the complete picture as it ignores the wide variation between the light traffic and heavy traffic condition while indicating reliability. On the other hand, the threshold used in on-time measures needs to be carefully defined as it does not vary linearly for every trip.

4. **Probabilistic methods** Figure 16 to Figure 19 show different probabilistic measures calculated for the case data, where the reliability status is indicated by the same color coding used earlier and cumulative curves. Figure 16 shows the $\Pr(\alpha)$ that determines the probability of trips that may take longer travel time than predefined travel time threshold where the higher value indicates greater unreliable condition. Van Lint et al. (2008) suggested 1.2 times median travel time as the threshold and also reported that it should be decided based on the interest of the analyst. In Figure 16, the probability was calculated by taking threshold as 1.1 median travel time, that is, $\Pr(\alpha = 1.1)$. From Figure 16, it can be observed that a few time periods in some sections are highly unreliable, with high relative spread of travel time (between median and median+10%). Also, it can be observed that the results are not consistent with statistical and buffer measures. This may be because it considers only median and 10% travel times above the median whereas buffer measures consider the variability in travel time between free flow and near maximum travel time. Figure 17 shows the AVV 2004 Probabilistic Measure [$\Pr(TT_i \leq 10 \text{ mins} + TT50)$], that determines if at least 95% of all travel times does not deviate more than 10 min from the median travel time for short routes (less than 50 km), while for longer routes, if 95% of the travel times are within a 20% margin around the median. Using the data under consideration, $\Pr(TT_i \leq 10 \text{ mins} + TT50)$ is calculated and observed that in all cases, the probability is greater than 95% indicating no unreliable periods. This measure could not capture the reliability condition as the threshold is too high for a finer level of spatial analysis as the case here (200 m sections). Hence, for very short routes or segment level analysis, the threshold has to be decided cautiously. Under probabilistic analysis of reliability, probability plots are also attempted. Figure 18 and Figure 19 show sample plots for a selected section to check hourly variations and for a selected hour to check spatial variations. From Figure 18, it can be observed that there is a wide spread in travel times, corresponding to evening peak hours and can be interpreted as unreliable periods as travelers may

Figure 20 Frequency of congestion (expressed in percentage).

experience large variation in travel times during these periods. Figure 19 shows unreliable sections at the sample hour such as section 6 and 7.

Based on the metrics calculated using probabilistic measures, it can be observed that these measures ignore the wide variation between the light traffic and heavy traffic condition while indicating reliability. Hence, they report results different from that of other sets of measures. Also, these metrics have a binary construction (either within or exceeds threshold). As such, these can be insensitive to small changes in the reliability condition, and hence, multiple bounds should be used to detect the changes effectively. Probability plots also may help to visually observe reliability under multiple thresholds.

5. Congestion based measures

Figure 20 shows a congestion reliability measure, Frequency of Congestion (FOC), where the reliability status is indicated by the previously used color coding. The threshold used here is travel time corresponding to a speed of 15 kmph. Thus, the numbers in Figure 20 shows the percentage of times the travel time exceeded the threshold travel time in the corresponding hours.

From Figure 20, it can be observed that section 7 and section 8 shows higher congestion frequency for most of the time periods. Along with these sections, it can also be observed that section 5 and section 6 are also prone to congestion during peak hours which are upstream side of section 7. Key point to note here is so far though few measures were able to identify the unreliability of section 6 during peak hours, none of the measures were able to identify section 5. Though this measure implicitly indicates unreliability, it can be more related to performance assessment rather than variability or reliability.

Agreement Among Reliability Measures

The agreement or consistency among measures is evaluated by carrying out a correlation analysis. Correlation can identify the strength of relationship or association between a pair of reliability measure. The correlation coefficient r ranges from -1 to $+1$. Here, 1 indicates perfect correlation and 0 indicates absence of linear correlation. Positive values indicate that if one measure increases, other increases and vice versa. Negative values indicate that if one measure increases, other decreases and vice versa. High-positive values imply high strength of relation among a pair of reliability measure. This can be directly related to similarity among the two measures about the reliability condition. Figure 21 shows the correlation between different pairs of measures discussed in the

	Std Dev.	Percent Var.	Width	Skew	UI	Buffer Time	BTI	Planning Time	PTI	On-Time Arr.	Misery Index	Pr(α)	FOC

Here UI is Unreliability Index, BTI is Buffer Time Index, PTI is Planning Time Index and FOC is Frequency of Congestion													
Yellow indicates high positive correlation and Red indicates low positive correlation or negative correlation													

Figure 21 Correlation between different pair of reliability measures.

previous sections. In the figure, yellow indicates high positive correlation and red indicates low correlation. Correlation coefficient above 0.6 is considered to indicate high correlation or strong agreement among measures.

From **Figure 21**, it can be observed that there is a strong agreement regarding the reliability condition among standard deviation, percent variation, width, buffer time, buffer time index, planning time, planning time index, misery index and frequency of congestion. These measures do agree well among each other. Skew, unreliability index, on-time arrival and $Pr(\alpha)$ do not agree well among each other and also with the other measures. However, this only shows linear relationship and if the measures are nonlinearly related, this will not identify that.

Overall, from the above measures and findings, it can be observed that many of the measures give different reliability indications. This may be due to the fact that some measures (1) use non-robust characteristics of the travel time distribution (2) do not explicitly take into account skewness of the distribution as an indicator of reliability. Future analysis can include comparison of private versus public transport reliability, link versus path reliability, and effect of intersection delay on reliability.

Introduction

A traffic incident is “any non-recurrent event, such as a vehicle crash, vehicle breakdown, or other special event, that causes a reduction in highway capacity and/or an increase in demand” (I-95 Corridor Coalition, 2007). Traffic incidents are regarded as a significant cause of non-recurrent congestion delays that motorists encounter daily on roadways. Road incidents account for 10%–25% of congestion in Europe (General, 2011). Traffic incidents normally consist of two intervals. The first one is from the time of occurrence to the time when the incident is cleared, and the second one is from the end of the primary interval to the time when the facility has resumed normal operations. Adler et al. (2013) demonstrated that a one-minute duration reduction generates a €57 gain per incident and even considerably higher gains at locations with high levels of recurrent congestion (i.e., approximately €1,200/incident/minute at highly congested locations). Although nonrecurrent congestion is difficult to predict because of its stochastic nature, addressing it in a timely and effective manner is important in reducing its influence on traffic conditions.

Traffic incident management (TIM) is “a planned and coordinated program to detect and remove incidents and restore traffic capacity as safely and as quickly as possible” (Carson, 2010). The goals of TIM are (but not limited to) as follows: reduce the time for incident detection and verification, response time, and clearance time; promote traffic safety; and provide timely and accurate information to the public (Amer et al., 2015). In the past few decades, various strategies and tools have been developed and implemented worldwide to improve overall TIM efficiency. An effective TIM strategy can reduce not only safety-related costs, such as reducing secondary incidents, but also nonsafety-related ones, such as reducing the duration of congestion caused by traffic incidents.

TIM Overview

The major TIM stages include detection, verification, response, site management, traffic management, motorist information, clearance, and recovery (Neudorff et al., 2003).

The following text provides brief descriptions of each TIM stage (Carson 2010; Amer et al., 2015).

- **Detection** is “the determination that an incident of some type has occurred” (Carson, 2010).
- **Verification** is “the determination of the precise location and nature of the incident” (Carson, 2010).
- **Response** is “the activation of a ‘planned’ strategy for the safe and rapid deployment of the most appropriate personnel and resources to the incident scene” (Carson, 2010).
- **Site management** is “the coordination and management of resources and activities at or near the incident scene, including personnel, equipment, and communication links” (Carson, 2010).
- **Traffic management** is “application of traffic control measures onsite and in areas affected by an incident” (Amer et al., 2015).
- **Motorist information** is “the communication of incident-related information to motorists who are at the scene of the incident, approaching the scene of the incident, or not yet departed from work, home, or other location” (Carson, 2010).
- **Clearance** is “the safe and timely removal of any wreckage, debris, or spilled material from the roadway” (Carson, 2010).
- **Recovery** is “the restoration of the roadway to its full capacity” (Carson, 2010).

TIM's stages have several other division methods. For example, the different phases in incident management in Europe are divided into various categories, such as discovery, verification, initial response, scene management, recovery, restoration to normality, and normality (General, 2011).

Performance monitoring is an important issue to improve TIM efficiency. In 2004, the National Traffic Incident Management Coalition (NTIMC) was launched in the United States to coordinate TIM-related experiences, knowledge, practices, and ideas. Then, national unified goals (NUGs) for TIM were developed; these goals encompass responder safety; safe, quick clearance; and prompt, reliable, interoperable communication (NTIMC, 2009). Many performance indicators can be used to measure the efficiency of TIM and different TIM stages. The following are several of the common performance indicators used to measure the TIM program (Carson, 2010; Owens et al., 2010).

- Roadway clearance time: "The time between the first recordable awareness of an incident (detection, notification, or verification) by a responding agency and first confirmation that all lanes are available for traffic flow."
- Incident clearance time: "The time between the first recordable awareness of the incident and the time at which the last responder has left the scene."
- Secondary incidents: "The number of unplanned incidents beginning with the time of detection of the primary incident where a collision occurs either a) within the incident scene or b) within the queue, including the opposite direction, resulting from the original incident."

In Europe, national road administrations normally acquire data related to the following performance measures: vehicle flow/congestion, journey times and delay, response times, and safety. The Federal Highway Administration has launched a TIM performance measurement knowledge management system¹ to provide TIM professionals with the knowledge and tools needed in successfully measuring TIM performance.

TIM Development Key Points

A good TIM procedure is critical for successful TIM. The development of the TIM procedure involves several key points.

Communication and Information Exchange

Effective information exchange is an important basis for TIM success and mainly answers the question, "how do different agencies involved in TIM collect and use data related to TIM?" Identifying and agreeing on a particular standard or group of standards for data exchange are necessary to ensure timely and reliable information exchange among all stakeholders in TIM. Several existing related standards, such as the National Transportation Communications for ITS Protocol, can also be used in TIM.

The I-95 Corridor Coalition developed and deployed an information exchange network in the 1990s to promote communication and information exchange among member agencies and users of transportation facilities (I-95 Corridor Coalition, 2008). In 2008, the Southern Traffic Incident eXchange program was deployed by the I-95 Corridor Coalition to facilitate incident notification/information sharing among the southern states of North Carolina, South Carolina, Georgia, and Florida.

In Europe, DATEX II is a standard for digital information exchange between road traffic management centers; in addition, the Transport Protocol Experts Group is a data protocol group for traffic- and travel-related information, and it can be used for reference in TIM (General, 2011).

Several successful information exchange projects for TIM exist worldwide; however, achieving real-time, multi-agency communication and information exchange in TIM encounters the following challenges (Owens et al., 2010).

1. Proprietary systems in different agencies are difficult to integrate due to incompatible standards, systems, networks, and frequencies;
2. Lack of standards for different terminologies or data dictionaries and presence of multiple and inconsistent entries for the same data fields;
3. Different attitudes and concerns about sharing sensitive data among different agencies; and
4. Cost-sharing between agencies of shared systems.

The following tools and strategies, which have been proven effective in overcoming these challenges, have been deployed in different locations (Carson, 2010; Owens et al., 2010).

1. Establishing agreements among different agencies to protect sensitive data
2. Establishing technical committees to develop common data dictionaries or translators
3. Establishing agreements regarding a defined standard or group of standards for information exchange
4. Establishing agreements regarding methods of integrating multiple formats of data for information exchange, including text, video, and audio
5. Promoting consistent data collection practices among various agencies

¹ https://ops.fhwa.dot.gov/eto_tim_pse/preparedness/tim/knowledgebase/index.htm

Traffic Incident Management System (TIMS)

With the development of various technologies worldwide, many traffic control centers in cities and highways have deployed TIMS. TIMS is an effective tool to deal with traffic incidents and alleviate the influence of traffic incidents on traffic conditions (Schrank and Lomax 2009, Owens, Armstrong et al. 2010) by reducing the time to detect incidents, the arrival time of responding vehicles, and the time necessary for traffic to return to normal conditions. In general, TIMS has the following functions.

Automatic incident detection: automatically provides incident detection by using computers, traffic detectors, and surveillance equipment in all weather and light conditions at all times. Accordingly, the time needed to detect incidents is reduced.

Provision of traffic information to stakeholders: provides different stakeholders with necessary information related to incidents through various technologies automatically and in real time (e.g., a computer-aided dispatch system).

Dissemination of traffic and transport information to the public: provides road travelers with information on incidents and guidance information on paths to follow through the incident area via various media.

Coordination of existing and future traffic control and surveillance systems: a TIMS will coordinate several traffic management systems, such as data collection systems, Mayday and Automatic Collision Notification Systems, real-time traffic information service systems (e.g., changeable message signs, CMS), and response unit dispatch systems, to support efficient TIM.

A typical TIMS is the Coordinated Highways Action Response Team (CHART), which started in the mid-1980s as the “Reach the Beach” initiative and now is a full-scale intelligent transportation system managed through a statewide operations center (SOC) functioning 24/7 and satellite traffic operation centers (TOCs) around the state (CHART, 2013).

The subsystems of CHART mainly include the following:

Traffic monitoring subsystem: supports the SOC and TOCs’ monitoring and control activities and mainly includes data communication facilities, closed-circuit television (CCTV) system, and other traffic-detection systems.

Traveler information subsystem: provides travelers with various information related to incidents through various means, such as CMSs on roadsides, traveler advisory radio transmitters, and mobile phones.

Incident management: supported in part by CHART emergency patrols, who assist all allied law enforcement agencies and fire/rescue departments in TIM.

Traffic management: assisted by the freeway management system and arterial signal system to effectively balance the capacity and demand during a traffic incident.

Many benefit analyses have shown that CHART is effective in achieving its mission.

Quick Clearance Legislation

Safe, quick clearance is one of the three NUGs and a strong priority for TIM. Quick clearance is a program used to remove temporary obstructions from the roadway for increasing the safety of incident responders, reducing the probability of secondary incidents, and relieving overall congestion levels and delay resulting from traffic incidents. Such a program is a key feature of all TIM responder actions, and a number of countries worldwide have implemented various quick clearance laws to assist in TIM. Generally, three types of legislation provide TIM responder authority for removing vehicles and cargo from incident scenes as quickly as possible (Carson, 2008; Owens et al., 2010).

1) Driver Removal or “Move It”

A number of countries have enacted laws that require motorists involved in minor crashes to move their vehicles out of the travel lanes and off the road to avoid blocking traffic when the vehicle is drivable and when:

- Only property is damaged in a crash.
- The accident has not resulted in any serious injuries or fatalities.
- One or more lanes are blocked by the vehicles involved in the crash.
- The involved vehicles can be moved without risk of further damage to property or injury to any person.

Driver removal or “move it” laws are particularly applicable to limited-access expressways.

2) “Move Over”

To protect incident responders, move over laws provide specific requirements for motorists approaching an incident scene. Vehicles are required to slow down and move over to an adjacent lane, when possible, to provide an increased safety buffer. In 2007, “Move Over, America” was implemented in America to promote the national awareness and enactment of move over laws.

3) Authority Removal

This type of laws provides statutory authority to designated public agencies to remove vehicles or other roadway obstructions out of travel lanes for restoring traffic flow. The removal authority’s scope, as an important strategy for reducing incident-related congestion and delay, has expanded to generally include obstructions not only on the travel lanes but also on the shoulder or the roadway right-of-way in recognition of potential safety hazards (Carson, 2008). Similar to driver removal laws, authority removal laws are mainly limited to incidents occurring on limited-access, high-speed roadways.

Recently, the quick clearance program has been implemented broadly and provides many potential benefits, such as reduction of nonrecurrent congestion delay, reduction of secondary incidents, responder protection, and minimization of improper or delayed responder actions.

Transportation Management Center (TMC)

Successful TIM relies on effective data collection, a suitable traffic control strategy, and information service. TMC is a useful tool to support these functions. Generally, TMC is a key technical and institutional hub to bring together various jurisdictions, modal interests, and service providers for focusing on the common goal of optimizing the entire surface transportation system. TMC is an important TIM resource and can be used as a hub of transportation management and control that brings together human and technological components from various agencies to perform various TIM functions. In the TIM program, a TMC or TOC's functions include the following (Krechmer et al., 2012; Tantillo et al., 2014):

- serve as a hub for the collection of incident-related information and play a critical role in incident detection and verification, such as using a CCTV system;
- notify and/or coordinate with multi-disciplinary responders;
- assess damage and the capacity of the transportation system around an incident scene;
- implement various traffic operation strategies to mitigate or manage traffic flow in the incident area;
- implement a traffic diversion strategy (if appropriate);
- disseminate real-time, accurate, and predicted traveler information related to incident status and traffic conditions to the public and media, such as sending messages to the CMS;
- continuously monitor traffic conditions at and around an incident scene and adjust TMC response and support actions when necessary;
- coordinate with other TMC/TOCs and response agencies regarding incident status and conditions;
- support the need for additional responses, such as those required for spill cleanup or serious injuries;
- support on-scene responses with motorist assistance patrols, traffic response teams, or emergency traffic control by motorist patrols;
- log various information related to incidents, such as detection, response, and clearance times;
- Stand down or revise traffic management strategies, support personnel, and traveler information systems as the incident clears;
- participate in postincident reviews and joint training at a later date;
- plan for anticipated events, such as winter storms and hurricanes.

TMCs have operation professionals who perform TIM functions and are usually operational at all times or at least during hours that cover the most congested periods. Effective use of TMCs' resources is critical to minimize detection, response, and clearance time.

Incident Command System (ICS)

Various responders must execute their respective roles and responsibilities in incident clearance at the incident scene to achieve successful, safe, and quick clearance of the traffic incident scene. ICS, as defined in the National Incident Management System (NIMS), provides an effective framework.

ICS was originally developed in the 1970s to manage rapidly moving wildfires. The system has evolved into a well-established, flexible, standardized on-scene management protocol specific for managing incident response activities in TIM as a key component of NIMS. "ICS is a standardized approach to the command, control, and coordination of on-scene incident management that provides a common hierarchy within which personnel from multiple organizations can be effective" (FEMA, 2017). ICS, as an important support for scene management in TIM, allows multiple response agencies to work together at an incident scene and use common terminology and operating procedures for controlling facilities, personnel, equipment, procedures, and communication (Amer et al., 2015).

NIMS normally specifies an ICS organization consisting of the following six major functions (FEMA 2017).

- Command — provide on-scene management and control authority: A single incident command structure should be used when an incident occurs within a single jurisdiction and without jurisdictional or functional agency overlap. A unified command structure should be used to improve unity of effort in multijurisdictional or multiagency incident management.
- Operations — direct incident tactical operations, which can be organized and executed in many ways based on the nature and extent of the incident, the jurisdictions and agencies involved, and the incident's objectives, priorities, and strategies.
- Planning — prepare an incident action plan (IAP), facilitate the IAP process, maintain resource status, and display situation information.
- Logistics — "provide facilities, security (of the incident command facilities and personnel), transportation, supplies, equipment maintenance and fuel, food services, communications and IT support, and medical services for incident personnel" (FEMA 2017).
- Finance and administration — track and analyze incident costs, record personnel time, negotiate leases and maintain vendor contracts, and account for reimbursements.
- Intelligence — gather, manage, and share incident-related information to ensure that intelligence and investigative operations and activities are properly managed and coordinated.

Traveler Information

Traffic incidents, which are nonrecurrent events, usually exceed the traveler's expectation and cause travel disruption. During traffic incidents, provision of information on traffic incidents helps reduce the traffic demand, decrease the potential for secondary incidents involving motorists approaching the incident scene, and improve responder safety at the incident scene; it also allows motorists to make informed decisions on the basis of current traffic conditions for minimizing the impact of traffic incidents (Robinson et al., 2018).

Information dissemination is an important part of TIM and generally includes pretrip and enroute travelers. With the development of information and communication technology, an increasing number of common approaches have been used to provide travelers information on traffic incidents. The general methods of pre-trip information may include websites, TV, radio, text or email alerts, mobile mapping applications, and specific apps released by transportation agencies. For en-route information dissemination, aside from the previously listed media, the other methods usually used are CMSs, highway advisory radio, and in-vehicle devices.

In-depth understanding of the kind of information that travelers need, the time that they need it, and the manner that they wish to receive it is necessary to provide full play to the role of traveler information services. To ensure traveler cooperation and information effectiveness, traveler information tools or strategies should ensure the following (Carson, 2010):

- Provide travelers the accurate nature and extent of incidents to ensure that they may make intelligent choices (e.g., delay or cancel their trips or select alternative routes or travel modes).
- Provide necessary information on possible actions, such as alternative routes.
- Accurately and clearly describe the required actions of drivers, such as reducing speed and lane changing or diverting.

The effectiveness of traveler information has been proven in many applications (Clark et al., 2017). However, inaccurate traveler information remains a huge challenge in TIM. Acquiring real-time and accurate information on traffic incidents and traffic conditions around the incident scene is sometimes difficult due to the lack of effective traffic detection and/or reporting system, miscommunication, or lack of communication. Consequently, accurate traffic incident-related information is difficult to provide.

Traffic Incident Duration Estimation (Li et al., 2018)

Traffic operators must understand the main factors that influence traffic incident duration and accurately predict such a duration to improve TIM efficiency. This research field has been investigated in terms of two subfields with different techniques: analysis of the factors that influence traffic incident duration and prediction of traffic incident duration time with or without influence factor analysis.

Analysis and prediction of traffic incident duration in TIMS and intelligent transportation systems are currently important topics that have produced different results in previous studies. Incident duration time is related to various factors, such as temporal characteristics (e.g., time of day, day of the week, and/or season), incident characteristics (e.g., number of vehicles involved in an incident, truck/taxi/pedestrian involvement, and number of deaths and/or injured persons), road characteristics (e.g., incident location and road condition), traffic characteristics (e.g., traffic volume), and weather conditions (e.g., rain, fog, and/or snow).

Various statistical methods have been traditionally applied to analyze and predict traffic incident duration time. Among these methods are the following: linear/nonparametric regression, Bayesian classifier, hazard-based duration model, discrete choice model, structure equation model, and probabilistic distribution analyses. A new research field that is based on data-driven empirical algorithms and supported by unprecedented data availability has recently emerged for traffic incident duration prediction with an increasing amount of published literature. Different data mining-machine learning approaches have been used to estimate and predict traffic incident duration time. These approaches include the following: decision and classification tree models, artificial neural networks, genetic algorithm, and support/relevance vector machine. Several researchers have recently begun to utilize a hybrid method of predicting traffic incident duration and applying the advantages of the aforementioned methods.

Others

In Europe, the following 10 points form the backbone of TIM practices (General, 2011).

- Speedy detection and response
- Good information on location, severity, and attendant hazards
- Protection of the scene and ensuring the safety of responders, victims, and the public
- Coordinated response with a clear structure of authority, roles, and responsibility
- Reliable communication between responders and the public
- Provision of appropriate equipment, facilities, access paths, and control centers
- Sufficient backup services to ensure speedy clearance and minimize congestion
- Training and debriefing systems
- Written guidelines and formal agreements when necessary
- Monitoring, performance assessment, and feedback into practice

In the United States, NTIMC has identified the following nine “keys to success” for TIM programs (CORPORATION, 2010).

- TIM program strategic plans
- TIM administrative teams (TIM team/task force)
- Performance measures
- Responder and motorist safety
- Response and clearance policies and procedures
- Procedures for major incidents
- Integrated interagency communication
- Transportation management systems
- Traveler information

Conclusion

TIM practices vary between countries. However, the success of TIM at any state-, city-, or local-level programs primarily depends on the active involvement of and coordination among different TIM responders. TIM practice must have the support of various advanced technologies to achieve success. For example, the application of photogrammetry can significantly reduce the time required to document an incident scene (Clark et al., 2017).

The project Pro-Active Incident Management in Europe recommends several promising techniques in TIM. In the monitor and anticipate phase, preincident management techniques based on novel technologies can be used, and these include video incident detection systems, vehicle-based information report (e.g., eCall), probe vehicle data (e.g., vehicle-to-infrastructure communication and floating car data), or the simulation-based incident response strategy planning tool. In the prepare and respond phase, incident management techniques can be used, and these include advanced eCall, professional on-site incident reporting, model-based short-term response planning, optimal clearing strategy, incident screens to avoid rubbernecking, redirection strategy (contraflow), and optimal lane closing strategy or dynamic speed limits and driver information.

A successful TIM program will lead to safe, efficient, and automated strategies for handling traffic incidents in the future if TIM-related responders and evolving innovative technologies have excellent coordination. The final TIM goal is “Successfully Managing Traffic Incidents Is No Accident” (Vásconez, 2013).

Traffic Incident definition

Traffic incidents are defined as nonrecurring events such as accidents, disabled vehicles, spilled loads, temporary maintenance and construction activities, signal and detector malfunctions, and other special or unusual events that disrupt the normal traffic flow and result in a capacity reduction of a facility (Srinivasan et al., 2003).

Incidents inevitably cause delays and reduce road capacity. According to one estimation, about 60% of the total vehicle-hours of delay on urban freeway was caused by traffic incidents (Lindley, 1987). In most urban areas, the situation is worsening with increasing traffic volume and limited expansion of the existing highway infrastructure. Moreover, incidents deteriorate road safety conditions. Congestions or traffic accidents caused by incidents have cost the world billions of dollars a year in the lost productivity, property damage, and personal injuries. According to the World Health Organization (WHO, 2018), road traffic injuries caused an estimated 1.35 million deaths worldwide in the year 2016, that is, one person is killed every 25 s. Thus, it is necessary to develop automated incident detection system to detect unexpected disturbance which are both reliable and quick to respond.

Automatic Incident Detection

Early detection of incidents is vital for formulating effective response strategy, and the benefits derived from effective and early incident detection that leads to prompt response can drastically reduce traffic delays, improve capacity and safety of road, and real-time traffic control. The previous studies have shown that 1 min early detected would reduce about 4–5 min delay (Srinivasan et al., 2004). The following diagram (Chung and Rosalion, 1999) illustrates the benefit of early detection

The function of Automatic Incident Detection (AID) is to automatically identify the occurrence of unpredictable incidents that affect the capacity of freeways so that appropriate response and clearance procedures can be executed to minimize the effects of the incident on traffic operation. AID algorithms work by detecting the change in traffic parameters measured at upstream and downstream detector stations. The working principle of the AID system consist of the following steps.

- Step 1. Receives real-time information from sensors;
- Step 2. Makes a decision whether an incident happening or not;
- Step 3. If so, give the alarms, and formulating effective response strategy;

A variety of sensor technologies are used to provide real-time traffic information for incident detection. These sensors commonly involve the use of inductive loop detectors (ILDs) and video sensors (Parkany and Xie, 2005). Video sensors become particularly important in traffic applications mainly due to their fast response, easy installation, operation and maintenance, and their ability to monitor wide areas (Kastrinaki et al., 2003). However, ILDs are the most commonly used sensors in traffic surveillance and management applications. In this chapter, most of AID algorithms introduced are based on traffic data collected from ILDs.

Methods of AID

AID Algorithms are a key component of a successful freeway traffic management system. Since the early 1970s, a variety of freeway incident algorithms have been developed based on traffic flow theory, pattern recognition, time series analysis, statistical techniques, and fuzzy logic, and Parkany and Xie (2005) reviewed the state of the art. After then, lots of new methods based on data mining and recently using deep learning were proposed to detect traffic incidents.

Pattern Recognition Algorithms

Pattern recognition-based algorithms rely on recognizing and differentiating unusual patterns of traffic from normal conditions. They compare the value of a traffic parameter, such as volume, occupancy, or speed, to preestablished thresholds. The algorithms trigger an alarm when parameters exceed the thresholds. Such kind of algorithms include California Algorithms, Berkeley (UCB) Algorithm, All-Purpose Incident Detection (APID) Algorithm, the Pattern Recognition Algorithm (PATREG), and Monica Algorithm developed in 1991.

California Algorithms (Payne and Tignor, 1978) were developed in the late 1960s for use in the Los Angeles freeway and surveillance control center, and ten modified versions of the California algorithm were identified and tested. The California #7 and California #8 provided the best overall results. Together with McMaster algorithms (Forbes, 1992), they are the most widely known and are often used as a standard for measuring the performance of other algorithms.

Statistical Algorithms

These algorithms use standard statistical techniques to determine whether observed detector data significantly differs from estimated or predicted values. It includes Standard Normal Deviate, and Bayesian Algorithm.

Standard Normal Deviate (SND) (Dudek et al., 1974) was developed by the Texas Transportation Institute (TTI) in the early 1970s. It is based on the premise that a sudden change in a measured traffic variable suggests that an incident has occurred on the freeway. Bayesian Algorithm uses Bayesian statistical techniques to compute the probability that an incident signal is caused by downstream lane blocking using historical data on the frequency of capacity-reducing events along a section of freeway.

Time Series and Filtering Algorithms

These algorithms smooth raw data over large time windows to eliminate short duration traffic disturbances such as random fluctuation, traffic pulses, and compression waves. Processed data are typically compared to predetermined thresholds. It includes Time Series ARIMA Algorithm, High Occupancy Algorithm (HIOCC), Exponential Smoothing Algorithm, Low-Pass Filtering, Dutch Algorithm and so on (Stephanedes and Chassiakos, 1993).

Time Series ARIMA Algorithm used an Auto-regressive Integrated Moving-Average (ARIMA) time series model to develop short-term forecasts and confidence intervals. Data that deviates from these predictions triggers an alarm. High Occupancy Algorithm inspects occupancy data for the presence of stationary or slow-moving vehicles, and examine several consecutive values of instantaneous occupancy to see if they exceed thresholds. Exponential Smoothing Algorithm utilized a single or double exponential smoothing function, which weights past observations to forecast future traffic conditions. It detects incidents using a tracking signal that is significantly different from that under nonincident conditions. Low-Pass Filtering algorithms removes sharp frequency data components, characteristic of noise in the data to produce a smoothed moving average. It uses direct comparison of differences in smoothed spatial occupancy over time to discriminate between recurrent congestion and an incident. Dutch Algorithm (Knibbe, 2004) detects the filtered average speed for the carriageway by means of an exponential smoothing filter.

Traffic Model and Theoretical Algorithms

These algorithms use complex theories of traffic flow to describe and predict traffic behavior during incident conditions. The model makes a decision whether an incident happened or not by comparing actual traffic parameters with the predicted output. It includes Dynamic Algorithm, McMaster Algorithm, and Low Volume Incident Detection Algorithms.

Dynamic Algorithm based on a dynamic model of traffic flow incorporates fundamental velocity-density and flow-density relationships into the detection analysis. The algorithm assumed that abrupt changes in a freeway system follow predictable patterns. McMaster Algorithm as well as modified version proposed a volume-occupancy template composed of four areas according to catastrophe theory (Persaud and Hall, 1989), each corresponding to a particular traffic profile. The algorithm performed two comparison tests between the template and actual loop data to decide whether traffic is congested and determined the source if congestion is detected. Low Volume Incident Detection Algorithms (Fambro and Ritch, 1979) developed by the Texas Transportation Institute used a speed input-output analysis of individual vehicles on freeway sections. The algorithm predicted the departure time of an entering vehicle and decided whether an incident happened based on the expected and actual output time.

Fuzzy Logic-Based Algorithms

Fuzzy Set Algorithms (Chang and Wang, 1994) incorporate inexact reasoning and uncertainty into the incident detection logic, which is designed to make decisions when data is imprecise or missing. This type of algorithm performed approximate reasoning by developing fuzzified boundaries. Whereas the "crisp" approach (e.g., California and McMaster) is basically a binary (0 or 1) decision process, the fuzzy approach shows the extent of the likelihood for an event. Some approaches use an occupancy trend factor and speed density comparison between neighboring detectors. However, membership functions are often set artificially, and this affects the performance of detection.

Data Mining-Based Algorithms

The rampant growth in traffic incidents has led to significant interest in the development of effective incident detection techniques in recent years, and various methods based on data mining have been proposed to address this problem, including partial least squares regression (PLSR), Neural Network, support vector machine (SVM), decision tree learning, rough set, ensemble learning, and so on.

PLSR (Wang et al., 2008) has been used as a classifier for AID. This approach builds a PLSR model to maps the relationship between the parameters depicting traffic flow and traffic state, that is the incident or nonincident state. The output of PLSR model tells whether an incident happened or not. In addition, a hybrid model which combines PLS and Neural Network has been developed to detect automatically traffic incident (Lu et al., 2012b).

Neural network approaches for incident detection have been thoroughly investigated and their potential superiority to other techniques has been demonstrated. Since 1990s, many different types of neural networks have been applied to solve incident detection problem (Ritchie and Cheu, 1993), including Bayesian-based Probabilistic Neural Network (PNN) (Abdulhai and Ritchie, 1995, 1999), probabilistic neural network (Wen et al., 2001), fuzzy-based neural network (Kim and Lee, 2005), fuzzy-wavelet radial basis function neural network (RBFNN) (Karim and Adeli, 2002), as well as combination of wavelet-based signal processing, statistical cluster analysis, and neural network pattern recognition (Ghosh-Dastidar and Adeli, 2003). The findings of previous studies indicate that neural network models have the potential to achieve better performance significantly in terms of detection rate (DR) and false alarm rate (FAR), as well as operational improvements in real-time incident detection over more conventional algorithms such as a series of California algorithms and McMaster algorithm.

However, all AID algorithms based on neural networks suffer from a number of shortcomings. First, it is a black-box model, thus hard to understand; second, it lacks transferability; another shortcoming is that its convergence depends on the selection of parameters, learning and momentum ratios, that have to be selected by trial and error. In addition, it is slow convergence and possibly being stuck in a local minima situation.

Incident detection is essentially a pattern classification problem, where the incident and incident-free traffic patterns are to be recognized. Any good classifier is a potential tool for the incident detection problem. Thus, decision tree learning, SVM, ensemble learning, rough set, as well as inductive logic programming, have been considered as alternative methods to develop some new AID algorithms.

Decision tree and grafted decision tree have been used to detect traffic incidents (Chen and Wang, 2009; Lu et al., 2014). As opposed to neural networks, decision trees have a top-down branched structure. Decision trees are not only efficient for classification, but also have an added advantage. Compared to other data mining algorithms, decision trees can easily interpret the rules used to filter datasets to their appropriate categories while simultaneously bringing to light the relative importance of different variables in the system being studied.

The rough set can cope with decision table and generate decision rules used for classification, therefore, the use of a rough set classifier has been investigated for freeway incident detection (Chen et al., 2007).

Inductive logic programming (ILP) is one of most famous inductive learning techniques, and the previous studies indicate that ILP is a competitive and promising method for traffic problems (Dzeroski et al., 1998; Roberts et al., 1998). Further study on ILP application to incident detection domain has been undertaken. Nfoil, one ILP system that combines naïve Bayes and foil, was applied to detect incidents, and their detection performance was compared with other existed AID algorithms (Lu et al., 2012a).

SVM classifiers have been investigated in AID problems with good results (Cheu et al., 2003). Like neural networks, SVM also has some drawbacks limiting its applications, since the performance of SVM depends on the choice of kernel function and several parameters, and setting the parameters of the SVM algorithm is a challenging task. Usually, an appropriate kernel function and parameters have to be chosen and tuned by trial and error. The ensemble learning is often more accurate than its individual components. Furthermore, it can avoid the burden of tuning the parameters for SVM or NN. Therefore, SVM ensembles, Neural network ensemble, random forest (Chen et al., 2007, 2009; Liu et al., 2013), and Nave Bayes Classifiers Ensemble (Liu et al., 2014) have been used to alleviate incident detection problem.

Imbalance Data Problem

In the real world, there are typically very few incident cases as compared to the large number of common traffic modes. Learning algorithms which do not consider class-imbalance, such as ANN, SVM, decision tree algorithms, tend to be overwhelmed by the major class and ignore the minor one. A heavily skewed data set often generates a classifier that predicts the minority class with a much higher rate of error than the majority class. This bias often makes the classifier highly accurate and completely useless at the same time (Chawla et al., 2004).

Traffic incident detection can be treated as a task of learning classifiers from imbalanced or skewed datasets, and the performance of traditional AID detector was restricted due to the imbalanced training set. Principal component analysis (PCA) as a one-class classifier for incident detection, which is constructed from the major and minor principal components of normal instances and a Support Vector Domain Description (SVDD) algorithm were brought into detect traffic incidents (Zheng et al., 2013). Another way is resampling by under sample, oversample or SMOTE to get a balanced training set, then learning some model from this training set, such as SVM, as a classifier to detect traffic incidents (Li and Chen, 2014, 2015, 2016).

Deep Learning

In recent years, deep learning technology has been applied to detect traffic incidents due to its excellent feature extraction and prediction capabilities. Zhang et al. (2018) compared and investigated deep belief network (DBN) and long short-term memory (LSTM) in detecting the traffic accident from social media data, revealing that DBN outperforms those of SVMs and supervised Latent Dirichlet allocation model. Singh and Mohan (2019) proposed a Stacked Autoencoder-based deep learning approach to detect road accidents using traffic surveillance video, which can automatically learn feature representation from the spatiotemporal volumes of raw pixel intensity. El Hatri and Boumhidi (2018) proposed a novel fuzzy deep learning-based traffic incident detection approach that considers the spatial and temporal correlations of traffic flow inherently, and the results revealed many advantages of the proposed model such as higher DR and lower FAR. Zhu et al. (2018) applied a convolutional neural network approach to detect incident that takes account of spatiotemporal network and traffic inherent structure, and validated that the detection accuracy of the CNN is generally superior to that of conventional alternatives.

Performance Criteria for AID

The performance of incident detection algorithms is often evaluated by the following statistical metrics, DR, FAR, mean time to detection (MTTD) (Cheu et al., 2003; Jin et al., 2001; Yuan and Cheu, 2003).

DR is defined as the ratio of the number of detected incidents to the actual number of incidents in the dataset, given as a percentage. If a single incident instance is identified within the period of actual occurrence, the incident case is regarded as detected.

$$DR = \frac{\text{number of incident cases detected}}{\text{total number of incident cases}} \times 100 \quad (1)$$

A pattern incorrectly classified as incident outside the incident occurrence period is considered as a false alarm. FAR is defined as the fraction of false alarm cases to the total number of nonincident instances.

$$FAR = \frac{\text{number of false alarm cases}}{\text{total number of nonincident instances}} \times 100 \quad (2)$$

Time to detection is the difference between the time the incident was detected and the actual time the incident occurred. MTTD is the average time to detect an incident over m incidents successfully detected:

$$MTTD = \frac{t_1 + \dots + t_m}{m} \quad (3)$$

Here, t_i is the length of time to detect the i th incident and m is the number of incident cases detected.

High DR, low FAR and MTTD are major requirements for AID models. In general, a more sensitive detection model has a higher DR, short MTTD but also higher FAR. There exist trade-offs between the DR, FAR, and MTTD. With these some conflicting performance measures, it is difficult to find the optimal incident detection model. For the purpose of comparing the detection

performance yielded by different AID models, a Performance Index (PI) that combines DR, FAR, MTTD, as well as CR has been suggested (Cheu et al., 2003):

$$PI = (1 - DR/100)^m \times FAR^n \times MTTD^p \times (1 - CR/100)^q \quad (4)$$

where CR is the classification rate, defined as the proportion of instances that were correctly classified based on total instances in dataset, written as

$$CR = \frac{\text{number of instances correctly classified}}{\text{total number of instances}} \times 100 \quad (5)$$

The coefficients $m > 0$, $n > 0$, $p > 0$ and $q \geq 0$, are used to emphasize the importance of each measure, respectively. Typical values for the coefficients are 1. Larger values denote greater importance of the particular parameter. A lower PI value indicates better performance.

Another PI modified is defined as follows (Chen et al., 2009):

$$PI = w_{DR} \cdot (1 - DR/100) + w_{FAR} \cdot FAR + w_{MTTD} \cdot MTTD/THD_{MTTD} + w_{CR} (1 - CR/100) \quad (6)$$

where w_{DR} , w_{FAR} , w_{MTTD} and w_{CR} are the normalized weights of corresponding measures, THD_{MTTD} can be interpreted as the threshold of MTTD, which can be derived from the statistic of MTTD in the past. This manipulation is to scale this measure into $[0, 1]$, the same scale to other measures.

Usually the weights of corresponding measures are taken equal to each other, except w_{CR} having a lower value, for DR, FAR and MTTD describe detection ability while CR describes classification ability, therefore, the formers are more meaningful and important than CR for evaluating the performance of AID algorithms, especially when the testing data set is highly screwed with rare incident instances.

The next criterion used is the area under the receiver operating characteristic curve, called AUC, which has been employed as a measurement of AID algorithms (Wang et al., 2008). The AUC is a numeric performance metric, which represents how separable two objects are. An advantage of this criterion is that it is not necessary to make any assumption on the prior probability of class distribution or specify the misclassification costs.

Introduction

Definition of Bottleneck

A bottleneck is defined as a road segment whose traffic capacity is lower than that of the road segments in its vicinity. The definition of traffic capacity of a road segment is the maximum traffic flow rate that can reasonably pass through the segment. Some evident examples of bottlenecks are lane drops, lanes blocked by car accidents, and signalized intersections with small green time ratios. Detailed discussions on types and mechanisms of bottlenecks are described in the further sections.

The Highway Capacity Manual (HCM) (Transportation Research Board, 2016) provides a detailed discussion on traffic capacity and the concept of a bottleneck from practical perspectives. According to the HCM, traffic capacity is defined as “the maximum number of vehicles that can pass a given point during a specified period under prevailing roadway, traffic, and control conditions. This assumes that there is no influence from downstream traffic operation,” and a bottleneck is defined as “locations where the capacity provided is insufficient to meet the demand over a given period of time” where “demand” refers to the flow of vehicles arriving at the bottleneck. The typical capacity of a basic highway segment is between 2250 and 2400 veh/h/lane, and that of a basic arterial segment with a signalized intersection is between 790 and 1110 veh/h/lane. These values vary among locations and conditions. Consequently, a location with a low capacity becomes a bottleneck.

Bottlenecks play an essential role in the description and understanding of traffic behavior, especially in uninterrupted flows (e.g., freeways, expressways). To be more precise, almost all of traffic congestions are caused by bottlenecks. Consider a bottleneck in an uninterrupted traffic. If an arrival flow rate (i.e., flow from the upstream section) to the bottleneck is larger than its capacity, then only a flow rate equal to the capacity passes through the bottleneck, and the remaining traffic forms a waiting queue at the bottleneck. A bottleneck is said to be active when it causes a waiting queue without queue extension from the downstream section.

See Fig. 1 for an intuitive illustration of a bottleneck. It shows an upturned bottle. The width of each cross-section signifies the capacity of the corresponding section. If an inflow is sufficiently large, the outflow will be limited by the neck. Further, the medium (i.e., the vehicles) that cannot pass through the neck will be pooled (i.e., form an waiting queue) upstream from the neck.

Macroscopic Mechanism of Congestion due to a Bottleneck

Typical congestion phenomena in uninterrupted traffic with a bottleneck can be explained as follows. Consider a freeway road section with a bottleneck. The inflow to the section can take two possible values: a flow less than the capacity (denoted as F1) and a flow greater than the capacity (denoted as F2). Congestion phenomena with time-varying inflow can be illustrated as in Fig. 2, based on the kinematic wave theory (Lighthill and Whitham, 1955; Richards, 1956; Newell, 1993), which is the most standard and simplest traffic flow model. Figure 2A shows the relationship between flow and density, where the solid curve indicates the fundamental diagram (Greenshields, 1935) of the section except for the bottleneck, the dashed line indicates the bottleneck capacity, and the black dots indicate the observed traffic states. Figure 2B shows a time-space diagram of traffic, where the horizontal

Fig. 1 Bottleneck and waiting queue.

Fig. 2 Typical congestion phenomena in uninterrupted traffic with a bottleneck.

axis indicates time (and toward the right indicates the future), the vertical axis indicates the space (and up indicates the downstream direction of traffic), and solid lines indicate boundaries between different traffic states. Regions F1, F2, and F3 are free-flowing and region C is congested. **Fig. 2C** shows the cumulative curves of traffic, where the upper curve indicates the cumulative vehicle number counted at the upstream end of the section (referred to as the arrival curve) and the lower curve indicates the cumulative vehicle number counted at the bottleneck location (referred to as the departure curve).

As shown in **Fig. 2B**, traffic at the bottleneck breakdowns (see the chapter "Flow Breakdown" for the details) when the arrival flow exceeds the capacity. As a result, a waiting queue ("C" area in **Fig. 2B**) is formed, and it keeps growing as long as the arrival flow exceeds the capacity. As soon as the arrival flow becomes less than the capacity, the queue starts to diminish. Thus, the severity of the congestion is determined by the bottleneck capacity and the demand (or arrival flow) profile.

The same phenomenon can be illustrated in a different way by cumulative curves (**Fig. 2C**). Note that the slope of a cumulative curve is identical to flow, and the vertical distance between arrival and departure curves denotes the number of vehicles between the

two locations. Thus, if the slope of the arrival curve exceeds the bottleneck capacity, the vertical distance between two curves increases, signifying the development of a queue, and so on.

In the flow–density diagram (Fig. 2B), an arrival flow that is less than the capacity is represented as a dot labeled F1, and an arrival flow that is larger than the capacity is represented by dot F2, and the departure flow when the bottleneck is active is represented by dot F3, and the traffic state in the waiting queue is represented as C. When traffic data is collected by a traffic detector, the observed traffic state will be completely different depending on the location of the detector. If the detector is placed at upstream next to the bottleneck, states F1 and C will be observed. If the detector is placed far upstream of the bottleneck, states F1, F2, and occasionally C will be observed. If the detector is placed at downstream of the bottleneck, states F1 and F3 will be observed.

By leveraging this theory, we can detect a bottleneck from detector data. Suppose that the detector on a basic road segment observed (almost) free-flowing traffic only, and its upstream detector observed both free-flowing and congested traffic. Then, we can presume that a bottleneck exists between these two detectors and can roughly estimate its capacity as the upper bound of the downstream detector measurement.

Fig. 3 shows the actual traffic detector data collected along a road section near Takarazuka-West tunnel, Chugoku Expressway, an intercity highway in Japan. The area has no major merge or diverge sections. It is clear from the data that a waiting queue formed between 900 min and 1280 min due to a bottleneck. According to the flow–density diagrams, the location of the bottleneck appears to exist between 20.3 km and 19.3 km locations, and its capacity is approximately 1500 veh/km/lane.

Sag and Tunnel Bottlenecks

What is Sag?

As noted in the first edition of the HCM (Highway Research Board, 1965), it has been known since the dawn of the traffic flow theory that the terrain type and grade can affect the traffic capacity. The main concerns in the HCM were the speed reduction of large vehicles and other adjustment factors that are caused by the grades. Since the early 1980s, it has been found that some of the sags and tunnels¹ that are the vertical alignment of a downgrade section followed by an upgrade section can become active as bottlenecks on freeways (Koshi et al., 1992). The traffic congestion caused by sags and tunnels is common in hilly regions and subaqueous tunnels (e.g. Lincoln Tunnel and Holland Tunnel, see Edie and Foote, 1958). It is claimed that the capacity at a sag is up to 25% lower than the expected value for the uninterrupted flow on a freeway (Koshi et al., 1992). In Japan, almost 60% of traffic congestion on freeways occurs at sags or tunnels (Xing et al., 2014), and considerable academic and practical efforts have been made that attempt to reveal the congestion mechanism and find the effective countermeasures. The next section describes the features of traffic dynamics at sags and tunnels, and its modeling approach. Practical control measures that can be taken to mitigate traffic congestion can be found in Management of Bottlenecks.

Features of Traffic Dynamics at Sags and Tunnels

A possible explanation of the bottleneck mechanism at sags and tunnels is as follows (Koshi, 1986): (1) As traffic volume increases, the utilization ratio of the inner lane increases; (2) Some vehicles on the inner lane slightly decrease the speed on the upgrade section of sags or at the entrance of the tunnel; (3) Vehicles with a higher desired speeds catch up with slower vehicles and are forced to follow them; (4) The number of vehicles following behind the moving bottleneck increases, generating a platoon in which traffic density is locally high; (5) Once a disturbance within a platoon occurs at a bottleneck section for some reason, the deceleration wave propagates upstream, and a breakdown in traffic flow occurs. As is shown in the Movie 1, which is the driver's view when passing through a congestion due to a sag, drivers cannot find any apparent causation for the congestion queue such as merging, diverging, weaving, lane drops, and work zones. In other words, it is quite unclear for drivers where the head of the congestion queue (i.e., bottleneck) begins. For this reason and due to an increase in gradient, drivers may be late in starting their acceleration and result in insufficient and bounded acceleration operation (see Fig. 4), which may cause a considerable capacity drop after the traffic breakdown (for more details, see the article "Flow Breakdown").

Modeling Approach

Several models have been proposed to represent the congestion that occurs at sags from both microscopic and macroscopic perspectives. In the microscopic approach, a number of car-following models have been developed that consider the gradient of the road and the effect of gravity. For example, in order to discount the acceleration for General Motor (GM) based car-following model, Koshi et al. (1992) considered the gradient term ($-\gamma \sin \theta$), in which γ is a sensitivity parameter and θ is gradient difference at sag. Goñi Ros et al. (2016) considered the additive acceleration term in Intelligent Driver Model (IDM) that depicted a driver's compensation behavior and in particular regarding his operation of the accelerator pedal in response to a gradient change at the sag.

The macroscopic approach is rather limited when compared to the microscopic approach. Jin (2018) developed a behavioral kinematic wave (first-order) model taking the location-dependent time gaps and bounded acceleration into consideration to

¹ Although a sag and a tunnel can each be a bottleneck respectively and independently, sags and tunnels are located close together in many cases. It is therefore difficult to separate the effects of a sag and a tunnel, so we do not distinguish them explicitly in this manuscript.

Fig. 5 Merge diagram. Note: Three black dots correspond to three possible states when the merge bottleneck is active. Each dot expresses a pair of mainline and on-ramp states, (mainline state, on-ramp state). Source: Reproduced from Daganzo (1995)

represent capacity reduction, capacity drop, and extremely low-acceleration rates. Wada et al. (2020) extended Jin's model to a second-order one to represent the temporal transition process and the formation mechanism of the capacity drop.

Freeway Network Bottlenecks

This section contains discussions on various types of freeway network bottlenecks such as "merge," "diverge," and "weave." The activation mechanisms using a macroscopic level modeling approach are discussed for each type. Please refer to the chapters such as "signalised intersections" and "signalised roundabouts" for urban network bottlenecks.

Merge Bottleneck

A merge bottleneck becomes active if the sum of traffic demands from upstream approaches (the total demand) exceeds the downstream traffic capacity. At an active merge bottleneck, a capacity drop likely occurs, and whether all or a subset of upstream approaches are congested depends on how the conflicting traffic streams share the downstream capacity. Such competing traffic flow behavior (under a constant downstream capacity assumption) can be explained by the following simple macroscopic theory (Daganzo, 1995), see Fig. 5.

Suppose a merging section has two upstream approaches (i.e., a mainline and an on-ramp), and the total demand exceeds the downstream capacity. In Fig. 5, a traffic state is expressed by a pair of mainline and on-ramp traffic flow rates. The solid lines indicate traffic states in which the traffic flow rate of both or either of the approaches equals to the capacity; if an initial state is located outside of these lines (i.e., demand exceeds capacity), the traffic state converges to a point on the lines as the initial state cannot be lasting. If both approaches have queues [(C, C) dot in Fig. 5], the traffic streams will merge according to some definite priority, that is, the traffic volume of each approach shares a constant percentage of the downstream traffic capacity. The ratio of the percentages of two approaches is called a merge ratio. Moreover, if the demand ratio is disproportionate to a fixed merge ratio, one of the approaches can be non-congested (i.e., the demand can be less than its capacity share). In this case, the other (congested) approach utilizes the remaining capacity [(F, C) and (C, F) dots in Fig. 5].

Fig. 6 Queue formation upstream of a diverge due to a fluctuation in traffic composition.

Is the merge ratio actually fixed, for example, irrespective of the severity of congestion? What is the main factor influencing the merge ratio? Cassidy and Ahn (2005) addressed the first question and they have observed that, at four merge sites in California, US and Toronto, Canada, upstream traffic streams enter a congested merge in some (nearly) fixed ratio. It suggests that the merge ratio mainly depends on merge geometry. Further, Bar-Gera and Ahn (2010) investigated 15 different merge sites in California and found that the merge ratio at each site can be reasonably estimated by its lane ratio (i.e., the ratio of the numbers of lanes of two approaches), which is similar to the capacity ratio proposed and (partially) validated by Ni and Leonard (2005).

Diverge Bottleneck

A diverge bottleneck becomes active if the traffic demand to either one of the downstream branches exceeds its traffic capacity. If all lanes of the upstream approach are queued (called a “one-pipe” traffic state) then the traffic that advances into not only the demand-exceeding branch, but additionally the others, experiences the delay equally due to the first-in-first-out (FIFO) discipline. Under FIFO, the specific arrangement and order (or composition) of vehicles with different destinations (i.e., different downstream branches) arriving at the back of the queue must be kept until the point of leaving the queue; thus, the discharge flows of non-congested branches can change significantly without a change in that of the congested one (Daganzo, 1995). The composition change can also cause a sudden traffic breakdown, even if traffic upstream of a diverge (i.e., the total demand) is steady, see Fig. 6.

While the above FIFO situation more likely occurs at an active diverge bottleneck with a narrow upstream approach, Muñoz and Daganzo (2002) showed that it could happen even at a wider one with a 5-lane upstream approach. The reference further showed that non-FIFO situations (called the “multi-pipe” traffic states) could persist for a long time. Congested multi-pipe traffic states, where queued lanes move at different speeds, possibly happen because drivers prefer different lanes depending on their destinations. Semi-congested traffic states, where some lanes are queued and others are not, also exist.

For modeling traffic behavior at a diverge, the simplified FIFO logic above (Daganzo, 1995) would be useful as a first approximation or for a large-scale network analysis. For a more detailed analysis, Daganzo (1997) and Daganzo et al. (1997) proposed a macroscopic multilane-multiclass theory that can approximate both FIFO and non-FIFO situations.

Weaving Bottleneck

Weaving is defined as the crossing of two or more traffic streams traveling in the same general direction. Weaving sections are formed when a merge area is closely followed by a diverge area, or when an on-ramp is closely followed by an off-ramp and the two are joined by an auxiliary lane (Transportation Research Board, 2016). At weaving sections, a lot of lane changes can occur, and their intensity and spatial distribution depend on the weaving demands and their geometrical features of weaving sections such as configuration, length, and width (the number of lanes) (see, Fig. 7 for examples). Several empirical studies showed that the lane changes (of the weaving traffic) are more likely to be concentrated close to the merge (e.g., Cassidy and May, 1991). Such a concentration makes the lane changes more disruptive and may trigger activations of weave bottlenecks.

Fig. 7 Examples of weaving sections.

Fig. 8 Dynamic lane assignment: a variable indication of lane role by flood light at Tokyo Metropolitan Expressway.

The impact of systematic lane changes on the capacity (or on the fundamental diagram) can be captured at a macroscopic level, as follows (Jin, 2010). For the duration of a lane change, a lane-changing vehicle occupies the current and target lanes. Therefore, the contribution of lane-changing vehicles to the total density should be doubled. In other words, lane-changing traffic effectively causes additional density, or equivalently, it causes a reduction in the effective number of lanes; and thus, the capacity reduces. In the same study (Jin, 2010), the capability of the theory was demonstrated by using vehicle trajectories by the NGSIM project (U.S. Department of Transportation Federal Highway Administration, 2016). Another explanation for the impact that lane-changing can have on overall traffic flow is that cautious lane changers at a weaving sections can act as moving bottlenecks that can cause a decrease in the overall traffic speed. With the bounded acceleration capability of lane changers, the moving bottlenecks can further contribute to the capacity drop (Laval and Daganzo, 2006).

Management of Bottlenecks

Current Managements

Numerous measures have been proposed or implemented to eliminate or alleviate bottleneck congestion. In this section, some of the typical measures are reviewed. The measures can be roughly categorized into two groups: supply-side measures and demand-side measures. Generally speaking, the former increases the capacity of a bottleneck, whereas the latter decreases the arrival flow to a bottleneck to prevent breakdowns and capacity drops.

The most direct and simple measure to alleviate bottleneck congestion is to physically increase the capacity of a bottleneck. This can be achieved by number of ways involving infrastructure construction, such as road expansion, lane addition, road geometry improvement, implementation of electric toll collection systems, and optimization of traffic signals. However, infrastructure construction is not always practically feasible because of cost or space limitations.

By introducing advanced traffic operation schemes, traffic capacity can be improved or congestion can be prevented. Such schemes are sometimes called as active traffic management. They mainly aim to increase the supply capability of the road operation without largely altering the road infrastructure. In the following text, notable examples of active traffic management schemes are introduced. Dynamic lane assignment, sometimes referred to as interchange merge control, is a control scheme in which the role of lanes is dynamically controlled, depending on the presence of nearby merging and diverging traffic, so as to improve efficiency of lane-changing. In Fig. 8, an actual implementation of dynamic lane assignment is shown. Lane change optimization also aims to improve efficiency of lane-changing at weaving sections in a more actively manner. It designates or informs drivers of optimal lane-changing locations (Mai et al., 2016). Hard shoulder running allows drivers to travel through a shoulder lane near a bottleneck section. It directly improves the physical capacity of a bottleneck.

As sags are the common cause of traffic congestion on freeways, several countermeasures have been taken in practice. Among the several countermeasures, a common idea has been to promote driver awareness and encourage drivers to accelerate more when they are on upgrade sections. Fig. 9 is an example adopted in Hanshin Expressway Route 3 in Japan, in which horizontal blue lines are painted on the walls to notify drivers that they are on an upgrade section. In addition, a signboard has been installed that indicates in words as well as with an illustration that the upgrade section continues for a further 300 m from this point. As another countermeasure, there has recently been an increase in the number of installations of the moving-light-guide-system (MLGS) shown in Fig. 10 and Movie 2 that creates a flow of LED light traveling with constant speed alongside the car and which stimulates the driver to match the speed of the light. The significant positive effects of MLGS on the traffic capacity have been confirmed in many bottlenecks. Currently, the possibility of further elaboration in operation and application of MLGS is being intensively investigated.

A variable speed limit intentionally changes the speed limit of particular section, especially in upstream sections of a bottleneck, at particular times. The purpose is to decrease the arrival flow to a bottleneck in order to prevent breakdown at the bottleneck. Therefore, it maintains free flowing of traffic and prevents potential capacity drops. Ramp-metering controls inflow to a highway at on-ramps to decrease the arrival flow to a bottleneck, as in the variable speed limit. High-occupancy vehicles or toll (HOV/T) lane scheme is a demand-side measure to decrease traffic volume while maintaining passenger volume. It designates some lanes as HOV/T lanes, so that a vehicle with fewer passengers cannot enter these lanes freely. Although HOV/T lanes do not directly increase the capacity of a bottleneck, it does however encourage efficient usage of vehicles and thus, decreases traffic volume in the long term.

Traffic demand management aims to control traffic demand and limit the arrival flow to a bottleneck to a value that is below the capacity. This is a demand-side measure. Variable speed limit, ramp-metering, and HOV/T lane can also be considered as a traffic demand management. Furthermore, information provision and congestion pricing are also used to manage traffic demand on a larger scale. By providing travelers with information on current and predicted travel times for various routes, travelers' route choices can be improved. For instance, if travelers can avoid congested routes, the resulting network traffic assignment might be efficient. However, the efficiency of the information provision scheme is limited in the sense that it only aims to achieve the user equilibrium or user optimal assignment, not the system optimal. Congestion pricing aims to achieve the system optimal assignment. Under congestion pricing scheme, drivers who travel particular road sections need to pay a particular toll, which is designed to achieve political goals such as the alleviation of congestion.

Future Management

In the near future, more advanced management will become possible because of connected and automated vehicles (CAVs). CAVs will change the behaviors of traffic. Furthermore, we will be able to use CAVs to control traffic.

At an operational level, capacity will be increased by CAVs. For example, cooperative driving of CAVs will enable platooning and stable car-following behaviors. The platooning of CAVs will drastically increase the capacity by shortening the headway. Stable car-following behaviors will prevent breakdowns and the propagation of stop-and-go waves. Furthermore, merging will be optimized by controlling the CAVs' lane distribution and entrance timing (Roncoli et al., 2015).

At a strategic and tactical level, demand will be optimized by controlling CAVs. For example, the choice of route and departure time of a CAV could be optimized so as to achieve the system optimal dynamic traffic assignment. In fact, this is possible by introducing a demand management scheme called tradable bottleneck permits (Akamatsu and Wada, 2017). It has been shown that bottleneck congestion can be completely eliminated by implementing this scheme in which "the road manager issues a right that allows a permit holder to pass through the bottleneck at a prespecified time period ('bottleneck permits') and let the permits be traded in a free market. This can be considered as an ultimate management system for bottlenecks as it eliminates all congestions.

Introduction

Flow breakdown is defined as a spontaneous transition from a free-flow state to a congested state of a traffic state at a certain location. “Spontaneous” in this definition means that the transition is not caused by a queue extension from the downstream sections. This occurs when the arrival flow to the location exceeds the capacity of the location. Therefore, a breakdown happens at a bottleneck (see the chapter “Bottleneck”). In the Highway Capacity Manual (HCM) (Transportation Research Board, 2016), breakdown is explained as “the transition from uncongested to congested conditions. The formation of queues upstream of the bottleneck and the reduced prevailing speeds make the breakdown evident.” and “breakdown occurs when the ratio of existing demand to actual capacity . . . exceeds 1.00.”

The definitions of free-flowing and congested states of traffic are as follows. Traffic is in a free-flow state when most of the vehicles are traveling at their own desired travel speed. On the other hand, traffic is in congested state when most of the vehicles are forced to travel at speeds lower than their desired travel speed, because of too small spacing (i.e., the distance headway is too small). Macroscopic traffic states can be divided into two qualitative categories: free-flowing and congested states. In general, traffic with a small density is free-flowing and traffic with a large density is congested. The threshold density between the free-flowing and congested states is called critical density.

Breakdown is a spatial-temporal phenomenon. Fig. 1 illustrates breakdown at a bottleneck, based on kinematic wave theory (for a basic interpretation of this figure, see the chapter “Bottleneck”). In the flow–density (or fundamental) diagram (Fig. 1A), breakdown can be represented as the transition from the free-flowing states (F1 and F2) to the congested state (C). However, this representation is not complete, because it is not clear where and when the transition happens. In the time–space diagram (Fig. 1B), breakdown can be represented as the onset of congestion at the bottleneck location. If a traffic detector was placed at the direct upstream position of the bottleneck, it would observe the aforementioned transition of traffic state from free flowing to congested. Note that this breakdown is not caused by a queue extension from the downstream sections; the downstream section is always in the free-flowing state. On a microscopic scale (Fig. 1C), flow breakdown can be roughly understood as the sudden speed reduction of a particular vehicle for which its following vehicles must also reduce their speed, although its leading vehicle is free-flowing. This speed reduction grows into a macroscopic waiting queue.

Characteristics of Flow Breakdown

Traffic congestion occurs when traffic demand exceeds traffic capacity. This seems to be an unquestionable fact and, pragmatically, it is true. However, observations of real-world traffic reveal that traffic flow is not as simple, due to its stochastic nature. Traffic demand varies stochastically, and even traffic capacity does. That is why flow breakdown does not always happen at the same traffic demand level even at a same bottleneck point.

Necessary Conditions for Flow Breakdown

According to Treiber and Kesting (2013), traffic flow breakdowns are caused by “the simultaneous action of three factors: high-traffic load, a bottleneck, and disturbances of traffic flow caused by individual drivers.” Fig. 2 illustrates this interrelationship. When traffic flow with a high density encounters a bottleneck, some speed disturbance may occur for a variety of reasons. If the high-traffic

Fig. 1 Breakdown in time-space and flow-density diagrams.

Fig. 2 Schematic representation of relationship between three factors and flow breakdown.

volume still continuously flows into the bottleneck, the disturbance remains there and is amplified. Then, a severe deceleration wave is generated and propagates upstream. Finally, traffic flow breaks down and the discharge flow rate from the bottleneck decreases (see section “Capacity drop” for details).

High-Traffic Load

Vehicles arrive at a bottleneck section randomly, not uniformly. This randomness is caused by the heterogeneity of time headways and desired speeds. A vehicle with a higher desired speed catches up with a slower vehicle and is forced to slow down and follow it. The number of following vehicles increases behind the slow vehicle, and then a platoon in which traffic load is locally and temporarily high is generated (Shiomi et al., 2011), as shown in Fig. 3. In a large platoon, speed disturbances at a bottleneck are likely to occur, propagate, and be amplified. This causes traffic flow breakdown.

On a multilane highway, traffic load is unevenly distributed lane by lane (Shiomi et al., 2015). When traffic density approaches critical density, more traffic is loaded onto the inner lane than the outer and center lanes, as shown in Fig. 4. Inequality in lane use results, at first, in a breakdown of traffic flow in the inner lane. Then, some of the overflow quickly moves to the less congested lane, thereby causing all the lanes to become congested almost simultaneously (Xing et al., 2014).

Bottlenecks and Local Disturbances

Local disturbances are likely to occur at a bottleneck or, conversely, we can say a bottleneck is the place where local disturbances frequently occur. On freeways, the cause of the disturbance at a bottleneck depends on the type of bottleneck. At a lane drop point, work zone, or accident site, where traffic capacity is apparently lower than the section behind the bottleneck, drivers are forced to change lanes and cut in at the bottleneck, which generate speed disturbances. At diverging and weaving sections, lane changes are necessary to get to the destination, which causes speed disturbances as well. At sags, tunnels, and even “rubbernecking” sites, drivers may unconsciously drop their driving speed, in turn stimulating any surrounding drivers to change lanes. Both speed drops and lane changes may cause considerable speed disturbance (Patire and Cassidy, 2011). For more details on a bottleneck refer to the article “Bottleneck.”

Stochastic Nature of Flow Breakdown

The breakdown flow rate, which is the flow rate at which traffic flow falls into breakdown and a congestion queue appears, varies even under the same road and environmental conditions, because each necessary condition mentioned above is not deterministic, but stochastic, and vehicle behaviors including freely driving, car-following, and lane changing are heterogenous. Thus, flow breakdowns are probabilistic events, and the concept of stochastic capacity has been proposed ([Brilon et al., 2005](#)). In this concept of stochastic capacity, the capacity distribution function $F_c(q)$ is defined and represented as follows:

$$F_c(q) = p(c \leq q), \quad (1)$$

where $p(\cdot)$ is the probability, c is capacity, and q is flow rate. In accordance with the definition of “deterministic” traffic capacity, that every flow rate greater than the capacity causes a traffic breakdown, the capacity distribution function $F_c(q)$ represents the probability of a traffic breakdown dependent on the flow rate q .

According to the HCM (Transportation Research Boards, 2016), the breakdown probability is estimated by allocating the observed volumes into groups, determining the ratio of the number of breakdown intervals and the total number of intervals for each group, and fitting that to the Weibull distribution. Herein, the fifteenth-percentile value of the breakdown probability is recommended to be the traffic capacity.

However, observed traffic capacity is considered as a type of censored observation. That is, when a traffic flow rate is observed without breakdown, it implies that the traffic capacity at that time is greater than the observed flow rate. This “direct” estimation is sometimes criticized because it ignores bias. To remove bias, a method to estimate breakdown probability has been developed, based on models for lifetime data analysis (Brilon et al., 2005). A non-parametric method to estimate the distribution function of lifetime variables is the so-called “Product Limit Method” (PLM), in which the capacity distribution function $F_c(q)$ is written as Eq. (2).

$$F_c(q) = 1 - S(q) = 1 - \prod_{i: q_i \leq q} \frac{k_i - d_i}{k_i}, i \in \{B\} \quad (2)$$

where q is flow rate [veh/h], q_i is flow rate in interval i (veh/h), k_i is the number of the intervals with a flow rate of $q \geq q_i$, d_i is the number of breakdowns at a flow rate of q_i , and $\{B\}$ is a set of breakdown intervals. For a parametric estimation, the distribution parameters are estimated by applying the Maximum Likelihood Estimation (MLE). Eq. (3) defines the likelihood function L :

$$L = \prod_{i=1}^n f_c(q_i | \beta)^{\delta_i} \cdot [1 - F_c(q_i | \beta)]^{1-\delta_i},$$

where β is a parameter vector of the distribution function of the capacity; n is the number of intervals; and $\delta_i = 1$, if interval i contains an uncensored value; and, $\delta_i = 0$, if interval i contains a censored value. Comparisons between the direct estimation, PLM, and MLE are illustrated in Fig. 5 (Geistefeldt and Brilon, 2009), which shows that the PLM and MLE gives more robust results than direct estimation.

Long-term Variations of Breakdown Flow Rate

Recently, it was reported that the breakdown flow rate has been gradually decreasing, over time, in some countries. Fig. 6 shows the long-term variation of the fifth-percentile value of breakdown probability, from January 2008 to December 2016, at nine typical bottlenecks on freeways in Japan (Shiomi et al., 2019). Fig. 6 indicates that the fifth-percentile traffic volume of breakdown probability decreased over time at eight of the nine sites. On average, the fifth percentile of breakdown probability decreased by 10.8 veh/15 min each year (i.e., 86.4 veh/15 min over eight years), which is equivalent to 91.7% of the initial value. The environment at these bottlenecks has remained unchanged in the eight years, so the decreasing trend may be attributed to the characteristics of vehicles, drivers, or both. This suggests that local disturbances are more likely to occur today than in the past, because the characteristics of traffic flow have changed.

Associated Phenomena and Their Possible Explanations

Peculiar traffic flow phenomena, associated with a traffic breakdown, are usually observed near an active bottleneck, which has negative effects on traffic efficiency and safety. Here, we will discuss two peculiar phenomena: “capacity drop” and “stop-and-go traffic,” and their possible explanations.

Capacity Drop

Once traffic breaks down at a bottleneck, one would logically expect that the queue discharge flow rate from the bottleneck is equal to its traffic capacity. However, in real traffic, the observed queue discharge flow rate decreases by an order of 10%. This phenomenon is called “capacity drop.” This phenomenon has been recognized for many years (e.g., Lincoln and Holland Tunnels, Edie and Foote, 1958), and the shape of associated flow-density relation typically resembles a mirror image of the lambda character (λ), which exhibits a discontinuity between the free-flow and congested states (see, for example, Koshi et al., 1983). The decrease in the queue discharge flow rate prolongs the congestion period, and can incur a profound additional delay of drivers, which has motivated development of several traffic control strategies, such as ramp-metering and variable speed limits.

The hypotheses for the occurrence of the capacity drop phenomenon are mainly divided into two categories, depending on assumed driving behaviors, that is, a (longitudinal) sluggish car-following behavior, and a (lateral) disruptive lane-changing behavior. Let us look at the latter category first. In Laval and Daganzo (2006), it is postulated that lane-changing vehicles create voids in (congested) traffic streams, and that these voids reduce flow. They describe this mechanism with a hybrid model in which lane-changing particles, endowed with a bounded acceleration (BA) capability, are endogenously generated and incorporated into the kinematic wave model as moving bottlenecks. Additionally, they found that the model can reproduce the capacity drop

Fig. 5 Input and output capacity distribution functions for simulation model. Source: Adapted from Geistefeldt and Brilon (2009)

Fig. 8 Illustration of the formation of the capacity drop.

phenomenon (see [Fig. 7](#)), in agreement with empirical observations at a merge bottleneck ([Cassidy and Rudjanakanoknad, 2005](#)). However, in [Cassidy and Rudjanakanoknad \(2005\)](#), it was also argued that “lane changing alone might not explain the capacity drop.” In fact, a significant capacity drop has been observed even in a single-lane freeway bottleneck ([Okamura et al., 2000](#)).

Regarding car-following behavior, it is commonly conjectured that a reduction in the queue discharge flow rate is caused by a low acceleration and/or delayed response of vehicles that leave from queues or traffic disturbances (e.g., oscillations), upstream of bottlenecks ([Hall and Agyemang-Duah, 1991](#); [Koshi et al., 1992](#)). One modeling approach assumes state-dependent changes due to different car-following styles. For instance, [Zhang and Kim \(2005\)](#) describes less sensitive responses to the leading vehicle in car-following models, by a state-dependent time-gap parameter, that depend on the distance-gap (and speed). [Chen et al. \(2014\)](#) also consider some drivers, who become less aggressive and adopt longer response times and minimum spacing when passing traffic disturbances, in their multiclass traffic flow model. However, none of these models treat the capacity drop phenomenon endogenously. Furthermore, because their mechanisms are purely based on (intra- and inter-) drivers’ heterogeneities, insights to the relation between the capacity drop and bottlenecks—spatial heterogeneities—are lacking.

Another modeling approach, which can endogenously describe the capacity drop phenomenon, is founded on two main assumptions: spatial heterogeneities and the BA of vehicles ([Jin, 2017, 2018](#)). The spatial heterogeneity is expressed by a location-dependent fundamental diagram. For example, the jam density diminishes within lane-drop bottlenecks. Additionally, the time gap may increase within sag (and tunnel) bottlenecks, because drivers cannot fully compensate for gradient changes, but try to keep their spacing. Such a location-dependent fundamental diagram describes not only the local reduction in the (static) capacity (i.e., bottleneck effects), but also the delay in the speed adaption to the leading vehicle in the car-following situation ([Wada et al., 2020](#)). As illustrated in a lead vehicle problem by [Fig. 8B](#), the BA version of [Newell \(2002\)](#)’s car-following model ([Laval and Leclercq, 2008](#)), with a specific location-dependent fundamental diagram, leads to a capacity drop. Specifically, if the demand exceeds the capacity, (1) the speed of a vehicle arriving at the end of the bottleneck (at $x = L$) is less than that of the leading vehicle, due to delayed speed adaption; and, (2) unlike in [Fig. 8A](#), the vehicle cannot recover to the free-flow speed instantaneously, owing to the BA constraint, which results in an increase in the headway of the next vehicle at $x = L$ (i.e., the queue discharge flow rate decreases). This vicious cycle [steps (1) and (2)] continues to reach the capacity drop stationary state. Furthermore, this modeling approach can explain a very low acceleration rate, when passing through the bottleneck, during the capacity drop stationary state ([Persaud and Hurdle, 1988](#); [Koshi et al., 1992](#)). [Fig. 9](#) demonstrates that the speed profile in the capacity drop stationary state, by the (calibrated) model ([Jin, 2018](#); [Wada et al., 2020](#)), very well matches that observed in the Kobotoke tunnel in Japan ([Koshi et al., 1992](#)).

Stop-and-Go Traffic

Once traffic flow breaks down, deceleration waves are formed around an active bottleneck and propagate regularly in the upstream direction, with an almost constant speed (on the order of 20 km/h). Vehicles are forced to decelerate and accelerate when passing through these traffic disturbances. This phenomenon is called “stop-and-go traffic” or “traffic oscillation,” and was first found in observations at the Lincoln tunnel (Edie and Foote, 1958). It is also known that the oscillations are rather small in amplitude immediately upstream of the bottleneck, but they are amplified as they propagate against the traffic stream; and, the oscillations across lanes are synchronized. Furthermore, Tian et al. (2016) recently found from empirical and experimental data that the standard deviation of the vehicles' speeds increases in a concave manner, during the oscillations (see Fig. 10). While the trigger of stop-and-go traffic can be caused by any traffic disturbance, such as lane changes and/or slow vehicles, there is still active discussion regarding the mechanism of the propagation and amplification of these disturbances.

Conventionally, stop-and-go traffic has been studied as a phase transition or pattern formation, due to the system instability (i.e., the string or flow instability) of car-following models, that are described as a system of (ordinary or delayed) differential equations (Kometani and Sasaki, 1958; Bando et al., 1995; Treiber and Kesting, 2013). This line of research indicates that, regardless of the details of the models, some common driving behaviors such as finite acceleration, deceleration, and reaction times lead to stop-and-go traffic (Treiber and Kesting, 2013). However, an empirical validation of these models is lacking (Laval and Leclercq, 2010). Furthermore, the growth pattern of oscillations, in the typical (homogeneous and deterministic) car-following models, is qualitatively different from the findings above (i.e., a convex growth pattern in the initial stage) (Tian et al., 2016).

Fig. 11 Vehicle trajectories of NGSIM data and simulation results. Source: Adapted from [Laval et al. \(2014\)](#)

A more behavioral modeling approach is based on extensive empirical analyses of vehicle trajectory data that is available more recently (e.g., NGSIM data, [U.S. Department of Transportation Federal Highway Administration, 2016](#)). Specifically, it has been proposed that oscillations may be caused by changes in the car-following behaviors of drivers when facing traffic waves. [Yeo and Skabardonis \(2009\)](#) proposed an asymmetric traffic theory in which acceleration and deceleration behaviors have different characteristics due to the anticipation and overreaction of drivers. In contrast to the introduction of the intra-driver heterogeneity, [Laval and Leclercq \(2010\)](#) proposed a car-following model with “timid” and “aggressive” drivers, as observed in empirical trajectory data. This study showed that combining a model, without an instability mechanism (i.e., the BA version of Newell’s car-following model, [Laval and Leclercq, 2008](#)), with such an inter-driver heterogeneity model can produce realistic oscillations.

The last but simplest modeling approach is to introduce human errors as random noise. The earliest model by this approach is by [Nagel and Schreckenberg \(1992\)](#), which reproduces stop-and-go traffic by a cellular automata model, with a breaking probability. More recently, [Laval et al. \(2014\)](#) simply added an acceleration noise, which is a function of road geometry, to the BA version of Newell’s car-following model, and found that the oscillations produced accord well with observation (see [Fig. 11](#)). Furthermore, [Tian et al. \(2016\)](#) showed that this model can reproduce the concavity of the disturbance growth well.

Future Direction

In the future, two innovations may occur regarding flow breakdown. First, our understanding of breakdown may be improved by using new data. Second, we may be able to control breakdown by using connected and automated vehicles (CAVs).

Conventionally, traffic data were mainly collected by traffic detectors that are fixed at a location, and their pulse data or aggregated data were used for analysis. Although they enabled us to understand basic properties of breakdown as reviewed in the previous sections, they have clear limitations. That is, they do not capture the continuous spatial-temporal dynamics of traffic. Because breakdown is a continuous spatial-temporal phenomenon that covers approximately one hundred meters and a minute, it is impossible to reveal the detailed, full picture of a breakdown by conventional detectors.

Recent advancements in information and communication technology enable us to collect new data that capture continuous spatial-temporal traffic dynamics. Proper use of these data will improve the scientific understanding of breakdown. Notable examples are as follows. First, complete vehicle trajectory data, obtained by fixed cameras and image recognition technology, are useful experimental data. The data captured the complete, continuous spatial-temporal traffic dynamics of specific road sections where the cameras were installed. For example, NGSIM data covers an approximately 600 m highway section for 15 min, and Zen Traffic Data ([Hanshin Exp. Co. Ltd., 2018](#)) covers a 2 km highway section for 1 hour. An example from Zen Traffic Data is shown in [Fig. 12](#). Second, sampled vehicle trajectory data, obtained by probes or connected vehicles equipped with positioning devices, are becoming common owing to the widespread use of global navigation satellite systems and smartphones ([Herrera et al., 2010](#)). Although they do not include complete information on the traffic (i.e., only sampled trajectories and speed), they can cover wide-

Fig. 12 Complete trajectory dataset obtained by series of video cameras on Hanshin Expressway, Japan. Top: aggregated traffic state. Bottom: trajectories near breakdown. Source: Data from *Hanshin Exp. Co. Ltd.*, (2018).

ranging areas. And third, sampled vehicle trajectory and spacing data, obtained by probe or connected vehicles equipped with ranging devices, will be useful (Seo et al., 2015). Those data capture local density and speed dynamics for wide-ranging areas, from which the complete, continuous traffic state can be estimated. An example of spacing data is shown in Fig. 13.

CAVs will enable breakdown to be controlled. As reviewed in the previous sections, breakdown is likely to be emerging from certain microscopic vehicle behaviors. Thus, by properly designing the driving behavior of CAVs, it may be possible to prevent or alleviate breakdowns. Especially, cooperative driving among CAVs may be useful, because it may enable efficient longitudinal and lateral movements which are impossible for ordinary human-driven vehicles. In-depth understanding of breakdown phenomena will be essential for breakdown prevention by CAVs

Fig. 13 Spacing data collected by probe vehicles near breakdown on Tokyo Metropolitan Expressway, Japan (Data from Seo et al., 2015). Red curves indicate trajectories of probe vehicles, and red areas indicate spacing between each probe vehicle and its leading vehicle.

Congestion and Bottleneck

Traffic congestion is one of the most concerning issues in the transportation system. Roadway sections are characterized by a maximum traffic volume safely passing within a specific time period (i.e., an hour); the maximum volume is the traffic capacity of the section. The capacity changes depending on various factors such as road geometry (e.g., number of lanes, grade) ([Transportation Research Board, 2010](#)), and along a roadway, different sections generally exhibit different capacity. The section with relatively lower capacity in comparison with upstream and downstream sections is identified as a bottleneck section. Typical values of roadway capacity are presented in roadway manuals. [Table 1](#) summarizes examples of freeway capacity and saturation flow rate of signalized intersections, respectively, cited from American and Japanese manual.

Traffic congestion occurs when the amount of traffic demand exceeds the bottleneck capacity, and the congestion forms a waiting queue towards upstream of the bottleneck. It usually is associated with the morning and the evening peak hours for commuting traffic ([Stopher, 2004](#)). As the capacity becomes insufficient for the traffic demand during the rush hours, traffic flow is no longer continuous but becomes interrupted at the bottleneck, then congestion occurs.

Efforts have been made to understand the cause of the bottleneck and congestion. A bottleneck can be roughly classified into two types: recurrent bottleneck due to static factors such as road geometries; and nonrecurrent bottleneck due to temporary conditions. The former includes junctions, intersections, sag sections, and tunnel. The latter includes traffic accidents, road works, adverse weather, and natural hazard. Consequently, traffic congestion is also categorized into two: recurrent congestion and nonrecurrent congestion ([Skabardonis et al., 2003](#)). Recurrent congestion occurs at the same place and the same time on a daily basis, especially on weekdays. It is the delay travelers regularly experience or expect at recurrent bottlenecks during known time of day such as morning and evening rush hour. Nonrecurrent congestion is less common and unexpected for road users; it occurs when nonrecurrent bottlenecks appear due to special events. Interest of this chapter is with the former: recurrent congestion ([Stopher, 2004](#)).

Recurrent congestion can be explained from two aspects. First, it causes due to the peak in traffic demand that exceeds the road capacity. Second, recurrent congestion arises because of a bottleneck. Remaining of this chapter describes the two causes of recurrent congestion.

Peak in Traffic Demand and Congestion

Recurrent congestion arises when peak of traffic demand exceeds the road capacity. The excess of traffic demand over the bottleneck capacity forms a waiting queue which develops towards upstream from the bottleneck. [Fig. 1](#) illustrates the typical distribution of demand over time of day with a peak, and with very small demand in the early hours. The capacity is presented by the dashed line in [Fig. 1](#). The congestion starts when the demand exceeds the capacity at time T_a and the excess of the demand continues until time T_b . The excess of the demand accumulates on the road forming a waiting queue. The queue, or the congestion, keeps growing in length between time T_a and T_b . Therefore, the queue length is maximum at time T_b when the traffic demand is lower than the capacity. As the demand gradually decreases after time T_b , the queue length becomes shorter; eventually the congestion dissolves at time T_c . It is noteworthy that the duration of congestion is relatively longer than the duration of demand exceeding over the capacity; the congestion can continue for several hours even when the demand exceeds the capacity for only an hour ([Koshi et al., 1989](#)). It is also observed that the excess of traffic demand over the bottleneck capacity is not necessarily high, approximately 12%–15% in freeways and a few percent in surface streets even when the congestion lasts for a few hours ([Koshi et al., 1989](#)).

Table 1 Base capacity of basic freeway segments and base saturation flow rate of signalized intersections in American and Japanese manual

	USA	Japan
Base capacity of basic freeway segments (PCU per hour per lane)	2300 ^a	2200 ^b

^aValue for multilane freeway sections for free-flow speed of 100 km/h.

**Figure 1** Peak demand and congestion.

Recurrent Bottlenecks

Bottlenecks on Freeways

Major bottlenecks on European or American freeways are located at merging or diverging sections where intense lane changing is observed. On the other hand, traffic congestion in Japanese freeways is generally triggered at sag sections or at tunnel entrances. This section describes the major recurrent bottlenecks on freeways (Oguchi, 2015).

Imbalanced Merging Section

Bottlenecks can be created at merging areas, when several roadways converge without corresponding increase in drive lanes (Falcocchio and Levinson, 2015). Examples of such lane imbalance are presented in Fig. 2, in which three lanes merging into two. A common cause of freeway congestion comes from where the number of entering lanes on two merging freeways exceeds the number of departing lanes, often observed at on-ramp sections. It is obvious that this condition results in recurrent congestion when the traffic demand surges, because number of vehicles from the upstream lanes exceeds the capacity of downstream sections after the lane convergence. As a result, intense congestion could occur during peak hours if inflow control strategies or mainline traffic controls, such as variable speed limit, are not implemented.

**Figure 2** Imbalanced merging section.

Figure 3 Weaving section and weaving traffic.

Weaving Section

Even when the number of lanes is balanced between upstream and downstream sections, recurrent bottlenecks near freeway junctions are major sources of traffic congestion. At the weaving sections, merging and diverging sections are closely placed and two or more traffic streams travel across each other (Transportation Research Board, 2010). Such lane formation requires intense lane changing behaviors for driver to access the lane appropriate for their desired directions. Fig. 3 depicts a typical formation of a weaving section. Drivers traveling the path B and path C must cross (weave) their ways. The vehicles traveling on the path B and C interact each other by the lane changings, and therefore cause speed reduction and the “capacity-drop” phenomenon. The significance of the capacity-drop depends on the weaving traffic volume; the higher the weaving volume is, the greater capacity-drop is observed at the section.

Sag and Tunnel

The bottleneck due to the capacity-drop phenomenon is also observed at basic freeway sections, where on-ramps or off-ramps are not present. It is reported that traffic congestion frequently occurs at sag sections and entrance of tunnels, accounting for 80% of all congestion in Japanese freeways (Xing et al., 2014). There is no merging or diverging at such sections, but slight speed perturbations due to slight changes in road geometries, such as gradients, cause speed reduction, and causes shock waves that propagates upstream, resulting in traffic congestion.

The sag sections have the vertical alignment with longitudinal slope changes from downgrade to upgrade. Since the sequence of slope changes causes disturbances in the speed of traffic flow, the capacity is lower at sag sections than in flat sections. The mechanism of the capacity-drop can be explained as follows (Koshi et al., 1992). A vehicle unintentionally slows down its speed at the start of the upgrade section due to insufficient acceleration. Then, the following vehicles are forced to decelerate accordingly, which generates a shockwave. The shockwave propagates towards upstream, and congestion occurs. As well, at a tunnel entrance, drivers tend to drive more carefully and slightly reduce their speed due to the sudden change of lighting conditions and the psychological pressure in the tunnel. Consequently, the capacity drop starts at the tunnel entrance, resulting in congestion as is the case at the sag sections.

Bottlenecks on Surface Streets

The most significant causes of congestion at surface streets are the bottlenecks at signalized intersections. The congestion at the signalized intersections is observed under oversaturated conditions, where traffic demand exceeds the capacity determined by signal control schemes. Oversaturated conditions can be defined as the state where part of vehicles in a waiting queue formed during a red light cannot be served during the next signal cycle. Once it occurs, the waiting queue keeps growing in length towards the upstream intersections; the queue blocks the exit of upstream intersections and reduce the throughput rate of the corridor.

Although several signalized intersections exist along a corridor, the bottleneck intersections that lead to traffic congestion are generally fixed. This is because the total green time per signal cycle must be shared among conflicting traffic streams. Traffic signals control the conflicting movements, and the share of green time is determined by the volume of different movements. If the higher traffic volume exists in the crossing direction, sufficient green time cannot necessarily be allocated to the other direction.

Furthermore, there is also a situation where on-street parking close to signalized intersections reduces the capacity of the intersection by blocking a lane available for serving traffic at the intersection. If an intersection has two lanes in a given direction, and when parked vehicles block one lane, there is approximately 50% loss in the capacity.

Summary

This chapter outlined the causes of traffic congestion and major recurrent bottlenecks. Roadway sections are characterized by traffic capacity, a maximum traffic volume that can safely passes within a specific time period (i.e., an hour); the section with relatively lower capacity is identified as a bottleneck section. Traffic congestion occurs at bottlenecks when traffic demand exceeds the bottleneck capacity. Recurrent congestion is the delay travelers regularly experience or expect during known time of day such as morning and evening rush hour, at recurrent bottlenecks where traffic capacity is reduced due to road geometries and traffic control devices. Major recurrent bottlenecks on freeway are located at merging and weaving sections, as well as sag and tunnel sections. At

merging sections, several roadways converge without corresponding increase in drive lanes as usually seen at on-ramp sections, and congestion occurs for the obvious reason; the capacity of the downstream lane cannot accommodate the number of vehicles from the upstream lanes. Weaving section is another source of recurrent congestion, where the capacity-drop phenomena occurs due to intense lane changing behaviors of driver. The capacity-drop is also observed at basic freeway sections, typically at sag and tunnel sections.

The most significant causes of congestion at surface streets are the bottlenecks at signalized intersections. Traffic signals control the conflicting movements, and the share of green time is determined by the volume of different movements. Signalized intersections can be recurrent bottlenecks when sufficient green time cannot be allocated because higher traffic volume exists in the crossing direction. Further, on-street parking vehicles close to signalized intersections also reduces the capacity of the intersection by blocking a lane available for serving traffic at the intersection.

Introduction

Nonrecurrent congestion results from a temporary decrease in capacity while the demand is unchanged, or it also occurs when the demand surges in nonperiodic manners. The primary difference between recurrent and nonrecurrent congestion is the predictability (Margiotta and Spiller, 2009). Recurrent congestion is predictable and typically occurs during the morning and evening peak hours in normal weekdays at bottlenecks due to static factors such as road geometries. On the other hand, nonrecurrent congestion is usually unexpected and hard to be planned for. It results from bottlenecks due to temporary capacity reduction caused by random or unplanned events, such as traffic incidents, inclement weather, and work zones. The nonrecurrent congestion also occurs by surge in demand during special events such as major sports events and recreational events. The occurrence of the nonrecurrent congestion varies both in time and location from day to day, and makes the transportation system unreliable. Obviously, when recurrent and nonrecurrent causes of congestion appear at the same time, their impact on delay are magnified. The amount of delay caused by recurrent causes and by and nonrecurrent causes is challenging to be estimated because the amount of delay produced by the two causes sometimes overlaps. Table 1 shows an estimate of the cause of recurrent and nonrecurrent congestion delay in the US freeways (Carvell et al., 1997; Falcocchio and Levinson, 2015). The estimate shows that nonrecurrent congestion generates a larger share of delay than recurrent congestion. Incidents are the major cause of nonrecurrent delay followed by bad weather, work zones, and special events

The focus of this chapter is on the following four main causes of nonrecurrent congestion:

- Traffic incidents
- Inclement weather
- Work zones
- Special events and other causes

Causes of Nonrecurrent Congestion

Traffic Incidents

Traffic incidents reduce roadway capacity and contribute to congestion occurrence. The amount of delay depends on the type and/or duration of the incident, the number of lanes blocked by the incident, the time to clear the incident location, and the time needed for the roadway to resume normal operation (Potts et al., 2014). Traffic incidents include not only vehicle crashes, but also refer to any events that remove one or more travel lanes from service, including stalled vehicles in travel lanes or on the shoulder. These events tend to block lanes, reducing the capacity of the roadway for vehicles driving by. Even incidents confined to the shoulder slightly reduce the capacity of the roadway, because drivers tend to slow down while passing by the vehicle on the shoulder. Estimates of the amount of roadway capacity available are provided in Table 2, as a function of number of lanes blocked by the incidents (Lindley, 1987). Even when an incident is located at the shoulder of the road, it reduces the roadway capacity.

Capacity reduction due to traffic incidents are also caused not only in the same direction of the incident location, but also in the opposite direction due to the drivers' behavior called "rubbernecking" that occurs when drivers slow down to observe a crash or anything else that may catch their eyes (Potts et al., 2014). The behavior decreases the operational speed of the roadway and also reduces capacity. An estimate conducted in American highways (Masinick et al., 2014) reported that the rubbernecking behavior at a crash site resulted in about 12.7% capacity reduction in the opposite direction of the accident where no lanes were blocked. Another observation of an accident site in Dutch highways (Knoop et al., 2008) revealed a sizable effect on traffic; the capacity decreased roughly by 50% in the opposite direction. At the position that provides the best view of the crash, the traffic begins congested, even though the road ahead is clear. The leader slows its speed to look at the accident site, creating a backward shockwave that propagates

toward the following vehicles. Once the backward wave reaches, the followers in the wave are also curious about the cause, so they too continue to slow down for a look. At the exact point of the crash, the traffic again begins to accelerate.

Inclement Weather

Driver behavior changes when weather conditions change. Rain and snow reduce visibility and cause drivers to reduce speed. The presence of snow and water on the road surface can also cause slick pavement that can increase slow traffic (Alfelor et al., 2009). Heavy rain and snow may cover the roadway, and hides road markings such as lane lines, resulting in longer headway as drivers move with caution; consequently, the roadway capacity significantly decreases. Among various weather conditions, the effect of rainfall on traffic has been intensively studied, and some reports on the capacity reduction effect. An empirical study conducted in Japanese metropolitan expressway clearly showed the decrease in free flow speed and in capacity with increasing amount of rainfall as presented in Fig. 1 (Chung et al., 2006). The capacity decreases by 4%–7% when light rain of 1 mm/h is present, and the larger

reduction up to 14% is observed for heavy rain condition. The Highway Capacity Manual (Transportation Research Board, 2010) provides capacity adjustments for different weather conditions. It shows that the capacity decreases by 2.01% in light rain with precipitation of up to 2.5 mm/h, and by 14.13% in heavy rain of over 6.4 mm/h, which largely agrees with the observation in Japan.

Work Zones

Work zones are sections on the roadway or roadside where construction, maintenance, or utility works are taking place. The degree to which work zones affect the capacity of the roadway is influenced by various factors; an investigation identified several important factors which can significantly affect work zone capacity (Weng and Meng, 2012), including the number of lane closures and work activity characteristics.

The capacity of a work zone is significantly affected by the number of lanes on the roadway as well as the number of lanes closed. The capacities of open lanes in work zones has been estimated as a function of the available lanes by using the data from literatures (Dixon et al., 1996; Transportation Research Board, 1985). Table 3 shows the example of the estimates of work zone capacity in urban area (Chin et al., 2004).

The work zone capacity is also affected by work activity characteristics, for instance work intensity. Work zone intensity has been classified into three levels: low, medium, or high (Karim and Adeli, 2003), and the work zone capacity can decrease as the work intensity increases from the lightest (e.g., guardrail installation) to the heaviest (e.g., bridge repair). The work time (daytime or nighttime) is another work activity characteristic which also affects work zone capacity. Night construction or maintenance could decrease work zone capacity because attention of drivers is reduced during the night time, according to an observation (Al-Kaisy and Hall, 2001). Work zone duration (i.e., short-term or long-term) is the third feature of work activity. In general, the capacity reduction in work zones is greater in short-term work zones than that in long-term work zones; short-term work zones can have a larger impact on the capacity because they are often unexpected, and drivers are not able to plan their trips to account for the delay they cause. However, the longer the work zone is present, the more drivers become aware of it and become familiar with congestion incurred by the work zone. Some drivers may start choosing alternative routes, and eventually the demand through the work zone is reduced. In addition, at the long-term work zone, frequent drivers become familiar with the configuration of the work activities, and thus the effect on the capacity can be minimized (Weng and Meng, 2013).

Special Events and Other Causes

Special events that cause nonrecurrent congestion often happen near arenas, stadiums, conference centers, and other large gathering spaces that host sports or music events, and large meetings. Special events tend to create large demand increase during the short period of time, usually just before the event starts and just after it ends. The higher traffic demand is also caused typically on weekends near vacation destinations. Another type of demand spike that could cause nonrecurrent congestions is that experienced during major evacuations.

Nonrecurrent congestion is also caused by malfunctions and/or suboptimal traffic control. Traffic control devices include traffic signals, ramp meters, speed limits, pavement markings, lane-use signs, and others. An example of nonrecurrent congestion due to a traffic control device that many drivers could experience occurs when a traffic signal malfunctions and goes to flashing operation, or when it becomes “out of plan” during a high demand period (Chin et al., 2004). Traffic may back up several road sections around the signal that is not functioning as it should. Traffic control devices can cause nonrecurrent congestion on freeways as well when traffic management devices such as ramp meters, or variable speed limit signs fail or malfunction.

Summary

This chapter described the causes of nonrecurrent congestion. Nonrecurrent congestion is incurred by temporary decrease in capacity due to unexpected events, or it also occurs due to sudden increase in traffic demand when major gathering of people takes place. Four main causes that have been identified in literatures are traffic incidents, inclement weather, work zones and special events/others.

Traffic incidents involves lane closures by crashed or stalled vehicles on travel lanes and the shoulder, reducing the traffic capacity at the incident location. As well, the incident causes capacity reduction on the opposite direction of roadway by the “rubbernecking” behavior of drivers observing the incident location. Inclement weather also reduces the capacity of roadway causing nonrecurrent congestion, because driving behavior changes under rain and snow due to reduced visibility and slick pavement. Third major cause of nonrecurrent congestion is work zones. The work zones usually block travel lane, and the capacity at the location decreases. Furthermore, drivers’ behavior varies depending on the characteristics of work activities, causing different effects on the roadway capacity. Finally, nonrecurrent congestion occurs during special events taking place; the events include sports or music events and large meetings where large traffic demand is created. Literatures have also identified that malfunctions or suboptimal traffic control could be a cause of unexpected congestion.

Introduction

The rapid growth in population and car ownership per capita significantly increases the amount of congestion throughout the transportation network in rural and urban areas. Traffic congestion is a day-to-day phenomenon that directly causes an increase in delay and fuel consumption at both freeways and arterials. Freeways and arterials are two subnetworks of the transportation network that complement each other. Freeways accommodate the mobility of the transportation network, while arterials accommodate the accessibility of the transportation network. One of the primary strategies of transportation agencies is to use the available Intelligent Transportation System (ITS) technologies and innovative data-driven strategies to provide and maintain an efficient transportation system that keeps a balance between mobility on freeways and accessibility on arterials. Through the Moving Ahead for Progress in the 21st Century Act (MAP-21), the US Congress requires that all the state Departments of Transportation (DOTs) and Metropolitan Planning Organizations (MPOs) periodically monitor and evaluate the safety and mobility performance of their jurisdiction's roadways. Generally, the overall performance of a transportation network is defined based on mobility and safety measures.

The mobility of people and goods is one of the essential objectives of an efficient transportation network. Mobility measures provide a base for transportation agencies to evaluate the current operational condition of the transportation network. Mobility information, in conjunction with the ITS technologies, can provide valuable information for both traffic engineers and road users. Travel time and vehicle speed are two of the indicators of transportation network mobility that can help to develop strategies to alleviate delays and congestion. Improving roadway safety and decreasing traffic crash frequency is another essential objective of an efficient transportation network. The number of fatalities, severe injuries, and property damage only crashes are the metrics proposed by FHWA for measuring the safety performance of the transportation network. These metrics provide insight into the DOTs and MPOs to establish and report their safety targets (Neuman, 2003).

A simple and straightforward solution to enhance freeways and arterials safety and mobility would be constructing new roads or adding additional lanes to the existing roads. However, due to the limited infrastructure and high construction cost, this solution is not always viable. Recently, with the advent of ubiquitous technologies and the emergence of modern traffic sensors, new approaches, and ITS technologies for improving mobility, accessibility, and safety in the transportation network are emerging. Active traffic management (Sullivan and Fadel, 2010, Mirshahi et al., 2007), restriping the freeway (Kondyli et al., 2019), ramp metering control strategies (Asgharzadeh et al., 2019), automated traffic signal performance measures (Chamberlin and Fayyaz, 2019), real-time crash prediction (Ariannezhad et al., 2018, Parsa et al., 2020), microlevel (Razi-Ardakani et al., 2018, Ariannezhad et al., 2014, Ariannezhad and Wu, 2018) and macro-level (Ariannezhad et al., 2020) safety analysis, crash prediction and hotspot analysis (Mansourkhaki et al., 2016, Mansourkhaki et al., 2017), Advanced Driver Assistance Systems (ADAS), such as automatic emergency braking, blind-spot monitoring, and integrity risk analysis of autonomous vehicles (Hassani et al., 2018, Hassani et al., 2019) are some of the innovative emerging approaches recently adopted by transportation engineers to enhance roadways mobility and safety. This chapter will primarily cover the recent efforts done by transportation agencies for monitoring and improving mobility at freeway and arterial levels. However, the safety component of transportation and its relationships to traffic operations is out of the scope of this chapter.

Freeway Mobility

Freeways are the main arteries that are aimed to create the highest level of mobility between regions, cities, and states. Commuters expect to move from an origin to a destination at free-flow speed with minimum delay. However, due to the nonrecurrent and recurrent traffic congestion, this is not always possible (Papageorgiou and Kotsialos, 2002). To tackle the freeway traffic congestion problem and conduct robust performance assessments, transportation agencies rely heavily on accurate and complete traffic data. Traditionally, traffic data was collected using on-road sensors such as pressure hoses, piezo-electric sensors, and inductive loops. Although collecting traffic data with on-road sensors is effortless, but the drawbacks with these types of data collection are limited

Figure 1 Travel time estimation methods and travel time applications.

coverage and high cost of implementation and maintenance (Leduc, 2008). In the past few decades, the emergence of new traffic sensors has significantly improved the traffic data collection process. Probe-based GPS data, video sensors, and floating car data are some of the most recent methods for collecting traffic data. However, the traffic data collected from these sources provide different levels of accuracy and completeness. Therefore, before utilizing the traffic data into analysis, data quality control tests need to be performed. Low quality and incomplete traffic data will negatively impact traffic projects' outcomes. The most common way to tackle the low quality and incomplete data is to use prediction (Duan et al., 2016), interpolation (Chen and Shao, 2000), statistical-learning (Ran et al., 2015) techniques, and hybrid models that include both prediction and statistical-learning techniques (Karimpour et al., 2019).

Travel time is one of the most crucial measures used for quantifying the mobility and efficiency of freeways and is directly impacted by freeway capacity. Oversaturated conditions severely disrupt traffic flow and increase the travel time by imposing massive delays on travelers (Asgharzadeh and Kondyli, 2018). However, travel time is not always available in broad spatial-temporal coverage to transportation agencies. Therefore, over the past decade, methods for estimating travel time have gained increasing attention. Regardless of the network size (freeway or arterial) or mode of transportation, travel time plays a significant role in transportation planning, design, and operation (Wu et al., 2004, Yang et al., 2016). Travel time data spans a variety of applications, including travel time reliability, quantifying freeway congestion, accessibility, and also for traffic safety studies (Yang et al., 2015). Fig. 1 illustrates a summary of different approaches for estimating travel time and its different applications.

Methods to estimate travel time could be categorized into direct travel time estimation (also known as measured travel time) and indirect travel time estimation. Traffic data collected from probe-based GPS data and test vehicles are commonly used for direct travel time estimation. In contrast, traffic data collected from existing traffic data collector infrastructures on the road, such as loop detectors and microwave radars, are generally used for indirect travel time estimation (Coifman, 2002). Traffic data collected from probe-based vehicles usually suffer from sparse and missing values and are usually labor-consuming. Therefore, indirect travel time estimation is preferred over direct travel time estimation (Yang et al., 2016).

Methods for estimating indirect travel time are classified into point-based and trajectory-based methods. Instantaneous model, time-slice model, and dynamic time slice model are three of the most known point-based methods used for estimating travel time (Cortes et al., 2002). Point-based methods assume that there exists a linear relationship between speed variability at upstream and downstream of a corridor. However, this assumption fails to consider the speed change within a corridor. Therefore, to improve the estimation accuracy, vehicle-trajectory-based methods were developed to improve the accuracy of travel time estimation. It is worthwhile to mention that both point-based and trajectory-based methods perform similarly under normal traffic conditions, but their accuracy will degrade significantly under congested traffic conditions (Yang et al., 2016).

Recently, researchers are focusing more on methods that are accurate even under congestion traffic conditions. This idea was initially proposed by Coifman (2002). Coifman estimated travel time by constructing vehicle trajectories using two-regime macroscopic models (Coifman, 2002). Later on, Yang et al. (2016), inspired by Coifman (2002), incorporated General Motors (GM) models to estimate travel time with less than seven percent MAPE under congested traffic conditions. Yang et al. (2016) evaluated their proposed model on the data collected from three corridors on I-270 in the Greater Saint Louis area. The results of their study showed that the GM-based travel time estimation model outperforms other conventional methods, such as the Instantaneous and Time Slice models. Fig. 2 is proposed by Yang et al. (2016) as the relationship between the GM-based model, macroscopic traffic models, vehicle trajectory, and travel time estimation models based on their work.

Figure 2 Relationship between general motors models, macroscopic traffic models, and vehicle trajectory and travel time estimation models. Source: Yang et al. (2016).

Recalling Fig. 1, estimated travel time could be used for estimating freeway travel time reliability (TTR), identifying freeway bottleneck, and as an input to Active Traffic Management (ATM) systems. TTR is a critical metric that is widely used for quantifying the mobility and efficiency of a freeway. TTR quantifies the level of satisfaction of the commuters and is the key to understanding on-time arrivals and delays. Generally, to estimate the amount of TTR segment-based or origin-destination-based (OD-based) methods are used. Segment-based methods are based on the estimated travel time data from fixed sensors (Yang and Wu, 2016, Yang et al., 2014). The OD-based methods estimate TTR based on the trip (origin and destination) travel time. For either approach, travel time, and travel time distribution need to be estimated (Yang et al., 2014). Gamma, Weibull, lognormal, Gaussian, and exponential (Polus, 1979, Emam and Al-Deek, 2006, Guo et al., 2010) are the most popular distributions used for fitting the travel time data. Guessousa et al. (2014) used six statistical distributions, Lognormal, Gamma, Burr (extended by Singh-Maddala), Weibull, a mixture of two Normal distributions, and a mixture of two Gamma distributions to estimate travel time. Then, they used the data collected from a two-lane urban motorway ring in France to conduct their study. The results of their study showed the superiority of using Singh-Maddala distribution in terms of quality of fit and practicality (Guessous et al., 2014). In another study, Yang and Wu (2016) used the data collected from an 8.1-mi segment of the I-270 southbound corridor and used Gaussian, Lognormal, and Gamma models to fit travel time data. The results of their statistical analysis showed that travel time could be more accurately fitted using mixture models. TTR, along with other reliability measures, has been widely used by different state departments of transportation for monitoring and evaluating the roadways. For instance, The Minnesota Department of Transportation used TTR to evaluate the effects of a ramp meter shutdown on Minneapolis St. Paul freeways (FHWA, 2017). Washington State Department of Transportation also used reliability measures for performance monitoring, reporting, and prioritizing their freeway's section improvement plans (Ishimaru and Hallenbeck, 1999).

Based on Fig. 1, estimated travel time data could also be utilized in identifying bottlenecks for quantifying the freeway congestion. Fluctuation in demand and the geometric design of the freeway are causes of recurrent bottlenecks. Meanwhile, nonrecurrent bottlenecks form due to traffic crashes, breakdowns, and other unpredicted events. Recently, extensive efforts have focused on identifying and characterizing both types of freeway bottlenecks. Based on the speed collected from a pair of upstream-downstream detector stations, the bottlenecks of a freeway can be identified simply by using oblique cumulative curves. Oblique cumulative curves are developed by subtracting a reference flow from the cumulative number of passing vehicles (Yuan et al., 2017). Speed counter maps are an alternative to the oblique cumulative curves that examine the overall picture of the traffic state in a segment of a freeway. Many transportation agencies, such as Caltrans Performance Measurement System (PeMS, 2017) and Portland Oregon Regional Transportation Archive Listing (PORTAL, 2017), are using speed counter maps. Another popular tool for identifying and tracking freeways bottlenecks is speed heatmaps. Fig. 3 is an example of a speed heatmap that visualizes the bottleneck hotspots over space and time. Fig. 3 visualizes the Spatiotemporal Congested Areas (STCA) along milepost 136 to 160 of I-10, Arizona (Ou et al., 2018).

Another application of the estimated travel time is in ATM systems (as shown in Fig. 1). ATMs are systems that control, monitor, and regulate traffic conditions with the primary goal of enhancing traffic safety and mobility (You et al., 2018). Variable Speed Limit (VSL) signs are one example of these systems that has gained much attention recently. Based on the traffic conditions, these signs dynamically adjust the posted speed limit. VSL signs are used to increase and homogenize the average headway, harmonize traffic flow, and reduce the speed variance (Ha et al., 2003, Abdel-Aty et al., 2006). The speed limit shown on a VSL is based on the traffic conditions upstream and downstream of the VSL (Grumert et al., 2018).

Other applications of travel time are real-time traffic monitoring, providing real-time route information to the commuters, and as a traffic condition indicator for traffic operation centers. It is worthwhile to mention that in order to have an efficient traffic network, transportation agencies need to develop strategies that can operate the freeways and arterials together as an interconnected system. The following section discusses the most recent efforts developed on enhancing arterial and local roadways.

Figure 3 Traffic condition over space and time. Source: *Ou et al. (2018)*.

Arterial Mobility

Arterials are the connector of the national transportation system to regional mobility. Arterials play a significant role in providing accessibility to residential and commercial neighborhoods and are essential to the regional economy and residents' quality of life. In the United States, arterials connect more than one million lane miles of roadways to the national highway system. According to the Urban Mobility Report by Texas Transportation Institute, traffic congestion on arterials caused commuters an extra 8.8 billion hours of delays, which impacted the fuel consumption of the users by an extra of 3.3 billion gallons of gas (TTI, 2019). Therefore, improving the arterials traffic conditions is an essential part of every transportation improvement plan. Local transportation agencies are actively seeking strategies and technologies to monitor, maintain, and improve traffic conditions at intersection and corridor levels.

Currently, more than 330,000 intersections with active signal controllers are operating in the US transportation network (Fehon and O'Brien, 2015). Traffic signals play an essential role in distributing the right of way among pedestrians, cyclists, passenger vehicles, and transit vehicles. Implementing correct signal timing provides direct and indirect benefits. Reduction in the delay and travel time are two of the most tangible direct benefits of signal retiming for commuters. The indirect benefits of signal retiming are reduction in fuel consumption, air pollution, pavement wear and tear, and motorist frustration, and enhancement in traffic safety (Schneider, 2011, Srinivasa Sunkari, 2004). Due to the rapid change in the traffic patterns on the arterials, transportation agencies need to retime and synchronize traffic signals periodically (Li et al., 2019). As soon as the traffic patterns change significantly, the performance of the traffic signals will deteriorate. Therefore, to address the change in traffic patterns, traffic engineers need to ideally re-evaluate the efficiency of the signal controllers and potentially retime the signals annually (Srinivasa Sunkari, 2004). However, many factors, including cost, availability of resources, and data availability, restrict transportation agencies from retiming their signals. Traffic data is a fundamental base for doing any signal retiming studies. Traditionally, traffic data was collected manually by humans. However, recently, traffic data is collected using intrusive (e.g., Loop detectors), and non-intrusive traffic sensors (e.g., video-based detectors) (Tang et al., 2015). Collecting traffic data using intrusive sensors is much easier and more manageable. However, intrusive traffic sensors are saw-cut into the pavement and will significantly deteriorate the pavement condition (Klein et al., 2006). Therefore, transportation agencies are actively seeking newer sensors or data-driven approaches for achieving necessary traffic data for developing signal timing plans.

Recently, video-based sensors are receiving increasing attention and are used in a wide variety of applications, including collecting real-time traffic data, real-time traffic monitoring, and surveillance (Semertzidis et al., 2010, Zhang et al., 2007). In order for the video-based sensors to collect real-time traffic data, such as turning movement counts (TMC), virtual-loop detectors should be configured at each approach. However, configuring these virtual detectors is a trivial and time-consuming task for engineers. Therefore, to avoid configuring virtual detectors, Advance Event Detectors (AEDs) are used (Li et al., 2019). Fig. 4 shows a virtual

Figure 4 A sample AED virtual detector in Tucson, AZ. Source: Li et al. (2019).

AED detector in an intersection in Tucson, Arizona. These AED detectors will ease the process of collecting TMC for the transportation agencies and will allow them to retune signal plans more frequently.

Another approach for gathering traffic data for signal retiming is to predict data based on the available and historical data. Recently, researchers are leaning toward using predicted data as a substitute for the real-time data for developing traffic signal timing controls (Min and Wynter, 2011). Methods for predicting traffic volume are either univariate (only considers the temporal feature of traffic), or are multivariate prediction (considers both spatial and temporal feature of traffic) (Wu et al., 2016). Historical averaging, time-series-based methods such as autoregressive integrated moving average (ARIMA) (Karimpour et al., 2017) are some examples of univariate traffic volume prediction methods. Spatio-temporal random effects (Wu et al., 2016), Spatio-temporal (ST) ARIMA (Kamarianakis et al., 2005) are some examples of multivariate traffic volume prediction methods.

Monitoring and regulating traffic at the corridor level are other crucial tasks for local transportation agencies. At the corridor level, average vehicle speed and speeding behavior indicate the performance of the corridor mobility. National Highway Traffic Safety Administration (2017) reported that speeding-related crashes account for more than 25 percent of all the fatality crashes (NHTSA, 2017). With the infrastructure limitation and the growth in vehicle ownership, agencies are required to develop the most effective and practical solution for tackling the speeding problems for improving mobility and safety at the corridor level. Speed Management Strategies (SMS) are one of the emerging ITS solutions that recently received considerable attention in different states. SMS are multi-disciplinary approaches that control and regulate vehicle's speed and speeding behavior using enforcement, road design, and technology applications (Bagdade et al., 2012). The NHTSA defines speed management strategies as a balanced program that involves the relationship between speed, speeding, and safety (NHTSA, 2006). The main goal of every speed management strategy is improve traffic mobility, public health, and traffic safety (NHTSA, 2014). An effective SMS should concentrate on four primary countermeasures: Education, Engineering, Enforcement, and Emergency services. Over the last 40 years, by educating drivers, public awareness has significantly raised, and improvement has been achieved in reducing fatal and injury crashes (NHTSA, 2014).

Engineering countermeasures influence driver speed choice and are usually categorized into traffic control devices, road and street design, and traffic calming approaches (Bagdade et al., 2012). Traffic control devices, such as speed feedback signs, advisory signs, Optical speed bars, and pavement marketing, are cost-effective approaches to reduce drivers' speed (Karimpour et al. 2020, Santiago-Chaparro et al., 2012). Reducing lane width and raised median are some of the road and street design approaches that have been proven helpful in reducing average speed (Gross et al., 2009). Speed hump, roundabouts, traffic circles, signal timing, and corridor progression are some of the proven effective traffic calming approaches (Halkias et al., 2017). Enforcement countermeasures are usually implemented on the location where it is critical to achieve and increase the posted speed limit. Onsite law enforcement is a common enforcement strategy that has been proven effective in reducing the operating speed and increasing the speed limit compliance (Stevanovic et al., 2011). However, one major drawback to law enforcement is the limitation of resources in many rural and urban areas. Emergency services include the response time of the emergency medical units and the care received by the victim after a traffic incident or crash has happened.

For commuters to experience high mobility, accessibility to local neighborhoods and businesses, transportation agencies need to invest in innovative traffic solutions at both intersection and corridor levels. It is worthwhile to mention that pedestrians, cyclists, passenger vehicles, and transit vehicles are the primary users of arterials. Therefore, the solution adopted by the local transportation agencies must consider all the factors impacting the quality of trip for multimodal transportation commuters, rather than just focusing on a specific group of commuters. The next section provides insight into the interface between freeways, arterials, and commuters.

Interface: Integrated Freeway and Arterial

Transportation agencies around the world are rapidly adopting innovative ITS technologies and data-driven strategies for utilizing the existing capacity of transportation facilities in order to improve traffic efficiency. Such ITS technologies and strategies have been shown in many studies to be effective. For instance, ramp metering and incident management are effective in reducing travel time by up to 48% and decreasing crash rate by up to % on freeways (Urbanik et al., 2006). Additionally, arterial management strategies such as Advanced Traffic Management Systems are effective in reducing travel time by up to 15% and decreasing emission by up to 13% (FHWA, 1996). However, the operation of freeways and arterials are closely linked together.

Lack of coordination between the freeway and arterial usually causes extreme inefficiency in the transportation system (Mahmassani et al., 1998). Therefore, state and local transportation agencies must work closely together on developing integrated strategies for monitoring and regulating traffic on both freeways and arterials (Urbanik et al., 2006). An efficient strategy could quantitatively and qualitatively investigate the potential interaction between freeways and arterials to maximize the total network throughput and reduce congestion (Wu et al., 2010). This emerging concept is known as “Integrated Corridor Management (ICM)” (Hardesty and Hatcher, 2019). ICM is a set of systems that help the transportation sectors to operate their transportation networks at the optimal level. The main goal of every ICM system is to efficiently and safely move people and goods, by collaboration between different transportation sectors, and integrating the current transportation infrastructures (e.g., freeway, arterial, transit, etc.) (Christie et al., 2015). Compared to traditional management strategies, ICM systems emphasize on coordinated, multimodal, cross-network transportation along various corridors within a region. In addition, ICM systems provide solutions to solve a variety of challenges within a region, including incident management, special event management, emergency management, and recurrent delays caused by incidents.

In 2006 USDOT selected five states (eight sites) as the pioneers for implementing ICM systems. The USDOT required the pioneers to define and select the initial technologies and approaches (such as ramp metering, congestion pricing, signal optimization, transit priority) for implementing the ICM systems in their regionwide transportation network. In 2017, the evaluation results of ICM implementation in three pioneers’ sites, Dallas, TX, San Diego, CA, and Minneapolis, MN, revealed a significant improvement in corridor mobility, congestion, and incidents management and reporting (Hardesty and Hatcher, 2019). The evaluation results show the effectiveness of ICM systems for monitoring and regulating traffic on both freeways and arterials. Although national deployment of ICM is not possible at the moment, the motivation to deploy ICM systems in transportation improvement plans are being considered among many regional transportation sectors.

This chapter summarizes the efforts done by different levels of Departments of Transportation for collecting traffic data and utilizing ITS technologies for enhancing mobility and accessibility at freeway and arterial levels. One potential direction to expand the contents of this chapter would be including the safety aspect of transportation into the discussion and to further evaluate the potential relationships between mobility, safety, and accessibility of freeways and arterials.

Concepts of Arterial Road Management

Arterial road management techniques are implemented by transportation professionals for coordinating the traffic to improve safety and operational performance. Classical management techniques on arterial roads, including signalized intersections, have been in use and proven effective for decades. At signalized intersections, traffic signals are now more intelligent and responsive to traffic demands through the use of systems such as loop detectors, video imaging, and tube sensors for signal actuation (Hoel and Garber, 2007). These intelligent systems use detectors to sense the presence of vehicles on a typical roadway approach, send this detection information to the road-side controllers, and initiate an optimized plan that minimizes specific performance measure(s) at the intersection. The concept involves the use of elements such as signal phase max out, minimum green time, maximum green time, and gap-out in designing signal timing plans (Hoel and Garber, 2007). This intelligent type of signalization is usually applied to isolated intersections and is often effective, especially under low traffic demand. Another concept in this regard is the adaptive traffic signal control (ATSC), which works based on the dynamic demand at intersections. Traffic signals can work as an offline approach, where the optimized signal timing is designed based on pre-collected traffic demand information (time-of-day plans), or as an online system, where the system is designed to actively collect vehicle arrival information and optimize the signal phasing and timing in real time. While these management techniques are effective for isolated intersections, they do not effectively consider closely spaced intersections, which are usually the case on urban streets. Under this condition, the coordination of successive signals is usually implemented (Fred Mannering et al., 2007).

Generally, the concept of *signal coordination* refers to the time synchronization of closely-spaced successive signals along a corridor such that the platoon of vehicles discharged from an upstream intersection arrives at the green phase of the downstream intersections, thereby vehicles proceeding through the coordinated corridor without stopping. In essence, by strategically setting the time difference between the start of the green phase for each successive intersection (*termed signal offset*), it is possible to create a continuum of green phases (*termed green wave*). This reduces the signal control delay by allowing more vehicles to arrive at each intersection during the green phases and fewer vehicles during the red phases, thereby consequently improving the corridor performance. To achieve this, controllers at each intersection in a corridor are connected with a master controller acting as a reference for the other local controllers using wired (fiber optic cables, coaxial cables) or wireless systems (radio communications). A

Figure 1 Signal coordination on a time-space diagram.

common method for time synchronization across intersections is using the master and local clocks, as will be described later (Urbanik et al., 2015). In the following sections, the elements of signal coordination, including the Time-space Diagrams, Signal Offsets, Bandwidth concepts, and Signal coordination complexities, are discussed. Thereafter, an outlook into various signal coordination frameworks and algorithms, including the currently implemented systems and emerging systems in terms of connected vehicle technologies, are provided. Finally, future trends and present limitations in the area of signal optimization and arterial traffic management are briefly discussed.

Elements of Signal Coordination

Time-Space Diagram

The Time-space diagram (TSD) shows the progression of signal indications and motion of vehicles along a corridor as a function of time (Hoel and Garber, 2007). It describes the technique for tracking the position of an individual vehicle or a platoon of vehicles over time, along with a one-dimensional specified distance. TSDs use the concept of velocity-time relationships to effectively evaluate the position of a subject vehicle within a segment, thereby allowing to coordinate the movement of vehicles with the phasing of successive signals. As a result, TSDs can be used to assess the relationship between vehicle movement, signal timing plans, and intersection spacing, and make modifications when necessary (Roess et al., 2011). They can also be used to assess other performance measures such as vehicle stops, green time arrivals, and queue lengths. Figure 1 shows a typical TSD (drawn to scale) connecting two successive intersections A and B. The time sequence is shown on the horizontal axis while the intersection distances are shown on the vertical axis. The line indicates the trajectory of a vehicle at each time t in the Northbound (NB) one-way street considered here. At A, the signal turns green at time $t = T1$. The subject vehicle moves a distance d_1 to intersection B, where the signal turns green at time $t = T2$. This progression continues for every possible intersection downstream of B. This phenomenon whereby vehicle platoons meet a green indication on arriving at each intersection is termed the *green wave*, and the time difference between each green indication is the *signal offset* (or simply *offset*).

Master Clock, Local Clock, and Green Wave

In a typically coordinated corridor, there are two types of clocks operating the system: the master clock (i.e., the controller, central system) and the local (individual intersection) clock. The master clock is the timing mechanism embedded within the controller logic relative to which the other downstream intersection local controllers are referenced in time, to generate the signal offset. The

clocks are expected to operate similar timeframes to maintain accuracy (Urbanik et al., 2015). Considering the TSD provided in Figure 1 and assuming the coordination starts at intersection A, the master clock will be located at A while the downstream local controllers will have individual local clocks. Each clock has a reference timestamp that vehicles are expected to get to the corresponding intersection. This synchronization of the master and the local clocks establishes the coordinated operations for the corridor. A closely related concept is the green wave. The green wave describes the continuum of green phases within a corridor (Hoel and Garber, 2007). Particularly for one-way streets, as shown in Figure 1, this indicates the start of the green phase at each downstream intersection on the arrival of vehicle platoons. Corridors with signal coordination have the same cycle lengths at each intersection to enable time synchronization for the start of green at each point, although the green time can vary at different intersections based on other factors. However, there are other slightly different signal progression concepts for two-way streets (Roess et al., 2011), which are described later.

Signal Offset

The signal offset is a major determining factor in the efficiency of signal coordination along a corridor. For every signal coordination design, the objective is to obtain an *ideal offset* for the corridor (Roess et al., 2011). The *ideal offset* is defined as the offset at which the first vehicle in the platoon reaches the downstream intersection exactly when the signal turns green. It defines the time relationship between the master clock and the coordinated downstream signals specified by the local clocks. Determining the offsets for a corridor usually considers factors such as the actual or desired travel speed of vehicles between successive signalized intersections, the distance, and the traffic demand on the corridor. The *ideal offset* ensures that vehicle platoons leaving an upstream intersection arrives at the downstream intersection towards the green phase or after minor street queues have been dissipated (Urbanik et al., 2015). To determine the *ideal offset* for each segment in a corridor, a combination of field review and TSD is recommended (Roess et al., 2011). For example, in the TSD provided in Figure 1, assuming no queue on the downstream intersection, the *ideal offset* between A and B can be calculated as the ratio of the distance (d_1) between the two intersections and the vehicle speed (S). However, this no-queue assumption is usually not the case as vehicles from nearby driveways or unserved vehicles from the last cycle may be queued at the downstream intersection. Under this condition, the *ideal offset* is adjusted for queues using Equation (1), where Q is the number of vehicles queued per lane, h is the discharge headway of queued vehicles, and l_1 is the start-up lost time measured for the downstream intersection (B) (Roess et al., 2011).

$$O_{adj} = \frac{L}{S} - (Qh + l_1) \quad (1)$$

Bandwidth

Closely related to Signal offset, Bandwidth (BW) refers to the time difference, measured in seconds, between when the first and the last vehicles in a platoon traverse the system without any of the vehicles stopping at any of the intersections (Hoel and Garber, 2007). The visualization of bandwidth on TSDs is effective for observing the behavior of signal coordination and assessing possible measures and their effectiveness in improving the system performance. While the TSD provided in Figure 1 shows the bandwidth for one-way street NB direction, it should be noted that if the same corridor were a two-way street, the bandwidth for the opposing direction could be different, and as additional intersections are added to the system, it becomes more complex to obtain a smooth progression like the one shown (Hoel and Garber, 2007). This, with other factors such as a change in traffic demand, or emergency vehicle pre-emption can affect the corridor Bandwidth. There are two important elements used to measure the performance of a Bandwidth: the bandwidth efficiency and the bandwidth capacity (Hoel and Garber, 2007). Bandwidth efficiency signifies how efficient the coordination is operating. It is measured as the ratio of bandwidth to the cycle length expressed in percentage, as shown in Equation (2). For conventional traffic, a BW efficiency of around 50% is considered reasonable. On the other hand, the BW capacity defines the number of vehicles per hour that can traverse a series of signals without stopping. Equation (3) gives the procedure for estimating BW capacity (Roess et al., 2011). An important parameter required for this is the BW itself, which can be estimated directly from the TSD as shown in Figure 1.

$$BW_{eff} = \left(\frac{BW}{C} \right) \times 100 \quad (2)$$

$$BW_{capacity} = \frac{3600 \times BW \times N}{C \times h} \quad (3)$$

where, BW = Bandwidth (s), N = number of through lanes in subject direction, C = cycle length (s), and h = saturation headway (s).

Signal Coordination Complexities

The TSD shown in Figure 1 depicts the signal progression on a typical one-way street. However, there are complexities and slight differences that occur with two-way streets. On one-way streets, signal progression can be described using four terms: simple progression, forward progression, flexible progression, and reverse progression (Roess et al., 2011). Simple progression occurs

Figure 2 Two-way street TSD representations: (A) Alternating, (B) Double-alternating, and (C) Simultaneous progressions.

when vehicles arrive at the beginning of the green phase on the downstream intersection. As such, the green wave proceeds in the forward direction with the platoon of vehicles, and it is also often called the forward progression (Roess et al., 2011). In cases whereby the simple progression on a corridor is revised at some time in the day, for example, to optimize for varying traffic demand or direction of flow, the scheme is referred to as a flexible progression. Finally, the reverse progression occurs when the downstream signal must turn green before the upstream signal due to left-over queues at the downstream intersection being too large and needs to be dissipated first before the arrival of the upstream platoon (Roess et al., 2011). The cases of two-way streets are slightly different, and complex based on traffic and geometric characteristics of both directions of the streets. Terms such as Alternate progression, Double-alternating progression, and Simultaneous progression are relevant in this case (Roess et al., 2011). The Alternate progression (Figure 2A) describes a corridor condition where the *ideal offset* is equivalent to half the cycle length (C). In such a scenario, an observer at the first intersection looking downstream sees alternating signal phases red, green, red, green, respectively, at the following intersections. The Double-alternating progression (Figure 2B) describes when the ideal offset is equivalent to quarter the cycle length. In such a scenario, an observer at the first intersection looking downstream sees signal alternate in pairs red, red, green, green, red, red, respectively at the following intersections. In Simultaneous progression (Figure 2C), all the signals in the coordinated corridor turn green at the same time. This is mostly used in very closely spaced intersections or high-speed corridors (Roess et al., 2011).

Signal Coordination Frameworks and Tools

Some representative signal coordination frameworks and tools are introduced in this section. These frameworks and tools use optimization-related approaches to find the combination of signal design parameters (e.g., offsets, cycle lengths, and phase sequence) that minimize performance measures such as vehicle delays and stops along the arterial while satisfying the necessary

Figure 3 Inbound and outbound bandwidth.

constraints, and ultimately improving the overall arterial performance. In this section, these frameworks and tools are classified into four parts: coordinating pre-timed signal control, coordinating responsive/adaptive control, signal timing and coordination software tools, and emerging concepts that integrate connected vehicle technologies. Each of these is discussed based on the common frameworks and tools used in practice. It is worth noting that the term “framework” is a general concept in this section for the sake of brevity, and some frameworks are originally defined as “hierarchical algorithm” or “control scheme.” Specific definitions are introduced correspondingly in the following subsections.

Coordinating Pretimed Signal Control Frameworks

MAXBAND

MAXBAND (MAXimum BANDwidth) was first proposed in 1966 (Little, 1966), and then in 1981 with a FORTRAN computer program (Little et al., 1981). It considers both the two-way corridor and network signal coordination with n signals $S_1, S_2, \dots, S_n$. For signalized corridor, MAXBAND designs different offsets for each signal to maximize the number of nonstop vehicles while crossing the corridor. Splits of corridor signals and speed ranges of each road segment are regarded as known inputs of the model, and the splits can be replaced with traffic flows and capacities. MAXBAND attempts to maximize the inbound bandwidth b and outbound bandwidth b with the given information, as shown in Figure 3. In the MAXBAND model, the problem is formulated as a mixed-integer-linear-programming (MILP) problem, and a branch-and-bound algorithm is employed to reduce the computational burden and improve efficiency. For network-level coordination, Little (1966) appends cycle constraints that connect the streets to expand the basic MAXBAND.

MAXBAND-86 (Chang et al., 1988), an extension of MAXBAND, was initiated by FHWA (Federal Highway Administration) to adapt the multi-arterial closed networks. However, both MAXBAND and MAXBAND-86 have the fundamental limitation that they do not consider the actual volume of each segment but the average directional volumes along the arterial. In other words, the model assumes almost all vehicles cross the arterial as platoons with rare turn-in and turn-out, not considering the possibility that the traffic volume may vary remarkably between different segments. MULTIBAND (MULTIple BANDwidth) (Gartner et al., 1991) is a significant extension of MAXBAND, which expands the MAXBAND to adapt varying traffic volumes by generating a variable-bandwidth progression. It also incorporates left-turn phase sequence optimization, cycle length optimization, speed limit optimization, and initial queue clearance time to improve flexibility. The heuristic method is included to accelerate computation. Stamatiadis and Gartner (1996) expanded MULTIBAND and developed MULTIBAND-96 to control of closed-loop networks.

PASSER V

PASSER (Progression Analysis and Signal System Evaluation Routine) was first developed by the Texas Transportation Institute (TTI) in 1973 (Messer et al., 1973). It was designed as an online arterial bandwidth optimization computer program that considers the multi-phase sequence. The PASSER II (Messer et al., 1974) was developed by TTI in 1974, and it is the widely known and long-lasting version of PASSER, while PASSER III (Messer et al., 1977) mainly focuses on signal timing optimization of diamond interchanges. PASSER V (Chaudhary et al., 2002; Chaudhary and Chu, 2011) is the latest version in the PASSER series of computer programs for the signalized corridor, network, and diamond interchange optimization. PASSER V uses three main optimization algorithms, including genetic algorithm, interference minimization, and exhaustive search, and divides the optimization process into multiple stages. The first stage determines green splits of each signal. The second stage decides offsets and cycle times for maximizing the bandwidth. The third stage adjusts variables to further maximize progression or minimize total delay.

Coordinating Responsive/Adaptive Control Frameworks

SCATS

SCATS (Sydney Coordinated Area Traffic System) was developed in Australia by RTA¹ (Roads and Traffic Authority) in the early 1980s (Sims and Dobinson, 1980). It is a real-time hierarchical adaptive traffic signal control system with three levels: local controller data collection from detectors, data processing, and then signal operations decision. The controllers control up to 200 signals to collect and analyze detector information and implement a real-time operation. With SCATS, the control center usually does not implement, or influence signal operations directly but only store essential traffic data and monitor the operation of the entire system. SCATS adjusts cycle length, splits, and offsets to minimize delay and stops or maximize throughput. At each cycle, SCATS collects traffic data from detectors at first, and the degree of saturation (DS) and link flow (LF) are calculated. Note that the DS concept is the ratio of effectively used green time to the total green time in SCATS, which needs to be distinguished from the widely used concept of degree of saturation defined by Webster (1958). The updated cycle lengths, phase splits, and offsets are calculated based on DSs and LFs. Since SCATS can be installed to manage numerous signals, it divides the entire traffic system into several small sub-systems of signals. Adjacent subsystems can link together to form some larger systems or even one large system based on a voting mechanism. If the cycle time requirement of the subject subsystem is close to the requirement of the adjacent sub-system (the difference is less than 10 seconds), a positive vote is made (Stevanovic et al., 2009); otherwise a negative vote is made. Votes are cumulated over time, and the adjacent subsystem can be linked if the number of positive votes exceeds four (Shelby, 2001). The system and subsystems can also be decoupled based on the same voting mechanism, if the number of positive votes is lower than zero (Shelby, 2001). This system design and corresponding mechanism provide more flexibility to the signal control system.

UTOPIA

Developed by Italian researchers (Donati et al., 1984; Mauro and Di Taranto, 1990), UTOPIA (Urban Traffic Optimization by Integrated Automation) is a decentralized hierarchical traffic control algorithm involving rolling horizon. Since the process of optimization is implemented in two layers separately, the area level control mainly focuses on the signal coordination, and the intersection level control consists of single intersection modules. The single intersection module is also referred to as SPOT. For every single intersection, SPOT collects real-time traffic data and optimizes signal plans by using a branch and bound optimization. There are two key components of SPOT; observer and controller. The observer updates the traffic state estimation of the intersection and communicates with each other. Using this information, the upstream arrival estimation can be utilized to support queue estimation. The controller determines and implements the signal operation in a rolling horizon manner. Originally the roll period is designed as 6 seconds, and the planning horizon is 120 seconds. However, the parameter set varies from different implementations. The area-level control (consisting of more than one intersection) also consists of two parts of observer and controller. The observer obtains entire area data and then predicts demand levels with a 3-minute interval. The controller optimizes traffic flow with a 30-minute planning horizon while acting on fictitious decision variables, saturation flow, and average speed. However, the details of UTOPIA are vague in the published literature.

SCOOT

SCOOT (Split Cycle Offset Optimization Technique) was developed in the United Kingdom by the TRL (Transport Research Laboratory) in the early 1980s (Hunt et al., 1981). It is a centralized adaptive traffic signal control system and has been upgraded several times (Bing and Carter, 1995; Bretherton et al., 1998; Bretherton, 2007). The latest version of SCOOT is SCOOT MMX (Bretherton et al., 2011), which adapts the TRANSYT traffic model to online applications and is usually considered as the online version of TRANSYT. SCOOT can optimize cycle lengths, splits, and offsets to minimize delays or stops. At each cycle, it collects traffic data from detectors, calculates the degree of saturation, and predicts arrivals and queues based on in-built models. Then splits and offsets optimized based on the traffic information correspondingly. For cycle length optimization, SCOOT considers all links' degrees of saturation within the given region. It is worth noting that SCOOT tends to gradually update the signal plan to avoid overacting, aimed at reducing the side-effect on traffic while adjusting signal plans.

RHODES

RHODES (Real-time Hierarchical Optimizing Distributed Effective System) was developed by researchers from the University of Arizona (Head et al., 1992; Mirchandani and Head, 2001). It is a hierarchical traffic adaptive signal control system that employs dynamic programming, decision tree, and rolling horizon. RHODES consists of two levels of control: intersection level control and network-level control. The network-level control decomposes the control problem into several sub-problems, which intersection level controllers will finally solve those sub-problems correspondingly. RHODES collects real-time traffic data to predict arrivals and queues to support signal optimization. At the network level, the REALBAND (Dell'Olmo and Mirchandani, 1995) is utilized to decide the constraints for network signal coordination. Based on the traffic information, RHODES predicts platoon arrivals within the given planning horizon and forms a decision tree to resolve conflicts among different phases. Therefore, a set of constraints will be generated and sent to intersection level controllers. At the intersection level, the Controlled Optimization of Phases (Sen and Head, 1997), a dynamic programming-based algorithm, is used to minimize accumulative delay based on specified constraints.

¹The RTA was abolished in 2011 and now is known as NSW Roads and Maritime Services.

ALLONS-D

ALLONS-D (Adaptive Limited Look-Ahead Optimization of Traffic Signals-Decentralized) was developed by researchers from the University of Michigan (Porche et al., 1996; Porche 1998; Porche and Lafortune, 1999). It is a decentralized real-time hierarchical adaptive signal control scheme, which employs dynamic programming, decision tree, and rolling horizon. The original ALLONS-D was expanded to adapt the network optimization with a two-layer scheme (Porche and Lafortune, 1997). Instead of using queue estimation and arrival prediction, ALLONS-D uses the real-time state of the intersection (named “snapshot”) derived from complex detector technologies, such as AUTOSCOPE (Michalopoulos, 1991). ALLONS-D uses a depth-first branch and bound algorithm to search the optimal control in the decision tree at the signal level. To coordinate signals, two different approaches are used: the hierarchical approach, and the iterative approach. Under the hierarchical scheme, it generally divides the accumulative delay of each intersection into two parts based on directions. The higher-level controller (e.g., arterial level controller) keeps updating and sending weights of each phase to local controllers to coordinate the signals to minimize arterial or network level delay. Under the iterative scheme, it incorporates a simulation model and attempts to obtain a set of coordinated signal policies by iteratively interacting with the simulation model. The effects on adjacent intersections are recorded during the simulation period, and the simulation will be terminated if the pre-defined equilibrium criteria are met. The iterative scheme is also regarded as ALLONS-I (ALLONS-iterative).

OPAC

OPAC (Optimized Policies for Adaptive Control) was initially developed by Gartner. The initial version provides three different approaches to solve the signal control problem, including dynamic programming (OPAC I), sequential optimization (OPAC II), and rolling horizon (ROPAC, Rolling horizon OPAC, or OPAC III). In 1996, the first coordination version of OPAC was proposed (Gartner et al., 1996; Gartner et al., 2001), which is called VFC-OPAC (Virtual-Fixed-Cycle OPAC, or OPAC IV). Andrews et al. (1997) also implemented OPAC-RT (Real-time OPAC) version 3.0 on Route 16 in New Jersey to support signal coordination between adjacent intersections. Gartner et al. (2001) further expanded the OPAC to adapt network signal control by implementing OPAC in RT-TRACS (Real-time Traffic Adaptive Control System). OPAC IV is a real-time hierarchical demand-responsive adaptive signal control scheme. It consists of three layers, including the local control layer, coordination layer, and synchronization layer. The local control layer implements signal operations in a rolling horizon manner and calculates optimal switching sequences while considering the VFC constraint derived from the synchronization layer. The coordination layer optimizes the offsets of each intersection within the mini-network every cycle. The synchronization layer is responsible for calculating network-wide VFC every few minutes, which can be pre-defined by users.

Signal Timing and Coordination Software Tools**TRANSYT-7F**

Developed by Robertson in 1969 (Robertson, 1969), TRANSYT (Traffic Network Study Tool) is one of the most common series of signal optimization tools. It is a computer program of traffic signal system simulation and optimization that optimizes cycle lengths, phasing sequence, splits, and offsets. All signals in the network generally use the same cycle length, except for allowing specified intersections to double-cycle (Shelby, 2001). To coordinate signals in the network, TRANSYT tunes offsets and splits by optimizing given objectives. In early versions, TRANSYT provides two major optimization objectives of delay and number of stops. In the latest version, TRANSYT-7F, it supports customized optimization objective function with different “performance indexes” (PIs) in terms of delay, progression, number of stops, fuel consumption, queue length, and throughput. TRANSYT-7F employs a genetic algorithm as the primary optimization algorithm. It aims to find the globally optimal solution with the given inputs while also incorporating multi-period optimization and direct CORSIM (corridor simulation) optimization (i.e., microscopic optimization). It provides two different simulation options, including link-wise simulation and stepwise simulation, for various purposes. The link-wise simulation is convenient for undersaturated traffic conditions, while stepwise simulation aims to handle oversaturated situations.

SYNCHRO

Synchro was developed by Trafficware, which the latest version is Synchro Studio 11. It is a delay-based software for signal timing analysis and optimization for arterials and networks. Synchro provides cycle length, phasing sequence, split, and offset optimizations. The main objective of signal optimization in Synchro is to minimize delays and stops and increase the efficiency of the traffic network. For signalized corridor optimization, Synchro optimizes splits and cycle lengths of each intersection first and then coordinates cycle lengths at the arterial level. Finally, it decides optimal offsets and phasing sequence and generates optimal signal plans. Those signal plans can be used as inputs of other traffic simulation software to further analyze the performances.

Integrating Emerging Connected Vehicle Technologies

The emerging connected vehicle (CV) technologies enable an early and periodical detection of approaching vehicles within the vehicle to infrastructure (V2I) communication range. Priemer and Bernhard (2009) proposed a decentralized adaptive traffic signal control strategy for urban networks using V2I communication. Similar to traditional signal control approaches, this strategy is also phase-based in a rolling horizon manner. Instead of collecting data from detectors, this strategy collects traffic information from vehicles equipped with communication devices every 5 seconds. Then, it calculates or predicts the queue length for the next

20 seconds, which depends on the penetration rate of equipped vehicles: if the penetration rate is 100%, the queue length is directly calculated; otherwise, a queue length estimation algorithm (Priemer and Bernhard, 2008) is utilized to estimate the queue length. It employs dynamic programming and completes enumeration in the optimization process to determine the optimal phasing sequence, in which the main objective is to reduce the total queue length. To coordinate signals, a priority strategy is implemented for main streams to reduce the number of stops. Each vehicle platoon (under high penetration) or single vehicle (under low or medium penetration) in the coordinated direction will be assigned a weighted factor q , and the value of q will increase according to the elapsed waiting time. Therefore, the green phase can be extended or early switched for coordinated direction.

He et al. (2012) proposed a platoon-based multi-modal traffic signal control framework PAMSCOD (Platoon-based Arterial Multi-modal Signal Control with Online Data), for signals within the traffic network under V2I environment. PAMSCOD considers two traffic modes, including transit buses and passenger vehicles, and assumes that signal controllers can obtain traffic data via V2I communication. A platoon recognition algorithm is also developed to identify pseudo-platoons with collected traffic data. PAMSCOD coordinates signals by considering the progression through downstream intersections. PAMSCOD uses mixed-integer linear programming to optimize signal plans based on traffic conditions, signal status, platoon information, and priority requests of buses, and the objective function is to minimize total weighted delay and total green rest time.

Islam and Hajbabaie (2017) proposed a decentralized coordinated signal timing optimization method under the V2I environment. Signal controllers can communicate with connected vehicles and collect traffic data. The main objective is to maximize the throughput and minimize queue length while considering traffic flow and adjacent intersections' decisions. Mixed-integer linear programming is introduced to solve the optimization problem. However, this study assumes the market penetration is 100% and has not proposed an algorithm to estimate unequipped vehicles' states. Therefore, the low market penetration scenarios may not proceed well with the proposed method.

Future Trends

Emerging advanced vehicular technologies, such as vehicle connectivity and automation, have great potential in managing arterial road management and benefiting traffic performance. In the past decade, the connected and automated vehicle (CAV) technologies have been developed and tested, proving the benefit brought by allowing signal controllers to obtain a high-resolution vehicle data and therefore enhancing the capability of perception of the traffic environment (Guo et al., 2019a).

Also, vehicle trajectories can be precisely controlled in addition to infrastructure-side control. A concept of signal-free intersections was proposed by Dresner and Stone (2008) for scenarios with 100% CAV market penetration in the traffic stream. Each CAV can plan its space-time trajectory and coordinate with others to resolve conflicts at the approaches and within the intersection, and therefore physical traffic signals are no longer necessary. Yu et al. (2019) proposed a corridor-level cooperative trajectory optimization with all-CAV traffic. Trajectory coordination and lane change behavior are explicitly considered at the microscopic level. A mixed-integer linear programming model was formulated to optimize trajectories along the corridor and, therefore, overall system performance.

However, it may take decades to reach the 100% CAV market penetration. Prior to that, signal optimization still needs to be considered carefully for unequipped vehicles, especially in the near-term future. For example, Feng et al. (2018) integrated signal control and CAV trajectory optimization and formulated a two-stage optimization problem. Dynamic programming and optimal control theory are applied to optimize signal timings and CAV trajectories correspondingly. Guo et al. (2019b) proposed a joint optimization framework that simultaneously optimizes CAV trajectories and signal timings under different CAV market penetrations. This framework forms a dynamic programming optimization problem and incorporates trajectory planning with piecewise polynomials (TP3) (Zhou et al., 2017; Ma et al., 2017) as a subroutine to improve the efficiency. Integrating signal control and vehicle trajectory planning and optimization under the CAV environment is promising and has great potential to improve traffic system performance. However, many questions need to be solved, such as how to efficiently optimize signal timings and CAV trajectories simultaneously in real time and how to extend joint optimization algorithms to arterials and networks. Communication disruptions, malfunctions of control and communication equipment, and cybersecurity issues also need to be further considered in the implementation.

Background

Traffic signals are used to control traffic and to avoid conflicts between road users, which are using the same road space (conflict area), for example, at grade intersections or pedestrian crossings. There are also several other implementation areas for traffic signals, such as traffic control at bottlenecks (e.g., at road construction sites), safeguarding of railway crossings, ramp metering at highway entrances or the exit of emergency service stations. Traffic signals can also be used to prioritize specific road-user groups and to meter the traffic entering an area or road section.

Traffic signal simultaneously guides all conflicting traffic streams of road users to pass a marked (or virtual) stop line or to stop and wait. A GREEN light authorizes vehicles to proceed. RED light is a negative signal indicating that road users are not allowed to proceed; they must stop and wait at the stop line. A YELLOW light (also called an amber light) gives road users a notice that the RED light will be signaled soon. It indicates that road users either have to stop at the stop line before the RED light appears or they have to pass and clear the conflict area as soon as possible.

Signal heads for motorized road traffic usually have three fields (RED, YELLOW, GREEN) which may be arranged vertically (RED on top) or horizontally (RED on the right or the left, depending on the driving side). In some special cases, signal heads with two fields or only one field can be applied. If the signal is addressing only specific traffic streams, then the signal light may show symbols for the respective road-user group (e.g., pedestrians or cyclists) or driving direction (e.g., left-turn arrow). Some of the examples of signal heads are shown in Fig. 1.

Traffic Signal Plan and Its Components

A signal plan consists of the signalization of conflicting traffic streams or modes at an intersection or crossing. A signal plan and its components for a typical four-leg intersection are shown in Fig. 2.

The GREEN time for each traffic stream depends on the cycle time, lost times (e.g., intergreen, start-up lost time) and saturation flow rate, which describes the number of vehicles that can theoretically pass the stop line within one hour of continuous GREEN time. The YELLOW time must correspond with driving dynamics (vehicle speed and braking performance), since, after the beginning of YELLOW, drivers need to decide either to stop safely in front of the stop line or to proceed and pass the stop line before the start of RED. Usually, the YELLOW time is set to a value between 3 s and 5 s, depending on the speed limit on the approach to the traffic signal. The RED time is not explicitly calculated, but it results from the other signal durations. Usually, the same signalization is repeated in a cycle with a duration defined as cycle time. During one cycle all traffic streams are given GREEN at least once.

Within one cycle, at least two or more stages (also referred as phases) can be defined as periods in which GREEN is given to one or more specific traffic streams, while all others have to wait. All streams given GREEN in one stage must be compatible streams (i.e., they do not have a common conflict area) or they must be at least partly compatible streams. For left-hand traffic shown in Fig. 2, the partly compatible streams are right-turn stream, that is, 3 and the opposing straight-through stream, that is, 8. In general, more stages allow a safer traffic operation. However, more stages also increase the number of stage transitions and the cycle time and therefore reduce the capacity of the intersection.

The stage transition (from one stage to another) must ensure that all road users of the ending stage have cleared the conflict area before any road user of the beginning stage reaches the same conflict area. In this context, the concept of intergreen times is applied.

Figure 1 Example of signal heads for (A) vehicles and (B) pedestrians.

Figure 2 Example of a signal plan for typical four-leg intersection. Source: Adopted from Tang et al. (2019).

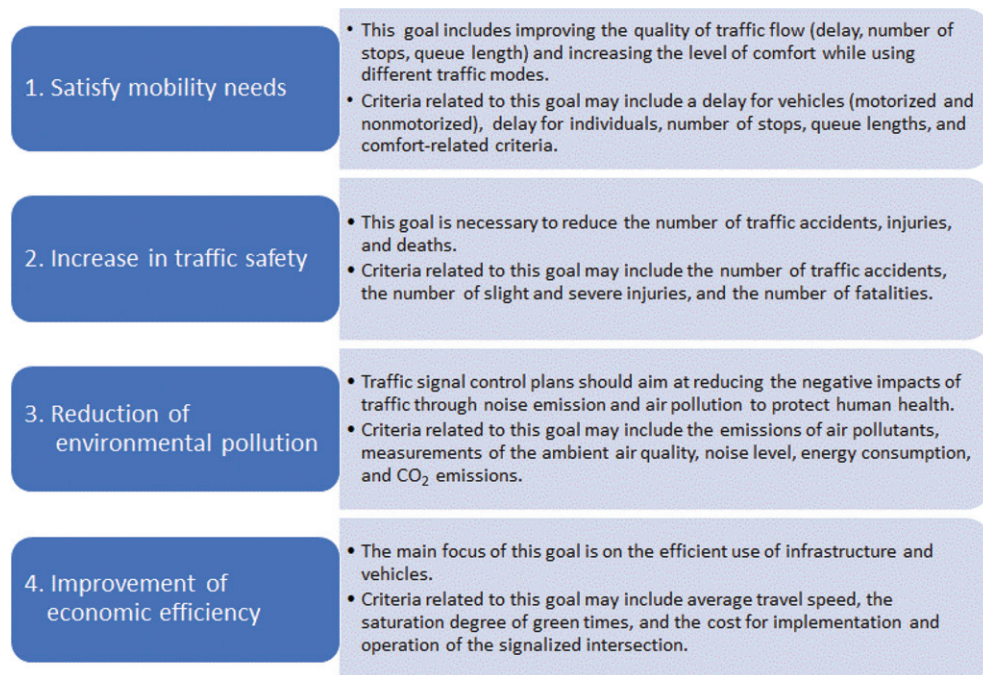

The intergreen time is defined as the time between the end of GREEN for one traffic stream and the beginning of GREEN for another stream, which is not compatible with the first stream.

The design of the signal plan has a serious impact on capacity, traffic safety, economic efficiency, and environmental compatibility. Statistics indicate that approximately 40% of total traffic accidents, about 80% of vehicle delays on urban roads, and nearly 20% of vehicle emissions occur at signalized intersections (World Health Organization, 2015; Federal Highway Administration (US) and Federal Transit Administration (US), 2017; Kan et al., 2018).

Goals of Designing Signal Plans

Usually, the impact of signals on all kinds of traffic modes such as motorized private transport, walking, cycling, and public transport should be considered for designing traffic signal plans. Furthermore, emergency vehicles and freight transport, especially heavy vehicle traffic, require special examination. The design of the traffic signal control should consider the various impacts on the different road-user groups as comprehensively as possible.

Following are four main goals within the framework of traffic management, which are generally relevant for all traffic modes (Boltze and Dinter, 1994):

Among aforementioned goals, due to the number of premature deaths caused by traffic-borne air pollution and traffic accidents, the prevention of emissions with adverse health effects and the improvement of traffic safety are recently gaining increased attention.

While designing a signal plan, the consideration of different goals or traffic modes can cause conflict. In some cases, the advantages regarding a specific goal or road-user group can only be achieved together with disadvantages for other goal or road-user groups. For a signal design, which would promote one traffic mode or a goal, besides the positive impact on this specific mode, the negative effects on other traffic modes or goals should be displayed and quantified, where possible.

For multimodal impact assessment, the same parameters regarding different traffic modes can be aggregated. For the evaluation of average delay, a person-related aggregation would be appropriate. Based on the average vehicle occupancy, the overall average delay for all road users at the intersection could be calculated (Hunter et al., 2011). Different weights could be assigned to the delay for different traffic modes to consider political preferences, comfort aspects of individual traffic mode, for example, operational aspects of public transport) (Boltze and Jiang, 2017). The signal design process gets further complicated when different modes have different priority levels of such as emergency vehicle priority, transit vehicle priority, etc.

Generally, it is also difficult to aggregate the impacts on different goals. However, it is necessary to find a fair balance of, for example, delay for different road users, number of traffic accidents, and health impacts of air pollution and noise. For fair trade-off among different objectives, multi-objective optimization traffic control models have been proposed in the literature. Researchers such as Sun et al. (2003); Hu et al. (2010); Costa et al. (2011); (Lertworawanich et al., 2011) proposed multi-objective models of fixed time that optimize different functions representing mobility needs such as average delay, the average number of stops, and maximum relative size of traffic jams. Similarly, studies (Wang et al., 2014; Zhou and Cai, 2014; Stevanovic et al., 2015) use multi-objective optimization to satisfy economic, environmental, health impacts and mobility needs simultaneous. Some research studies (Schmöcker et al., 2008; Stevanovic et al., 2011; Rakha and Abdelghaffar, 2019) apply multi-objective optimization to control different modes such as Bicycles, Buses and Cars. Various solution algorithms such as genetic algorithm (GA), ant colony optimization (ACO) algorithm, and particle swarm optimization (PSO) algorithm have been implemented to solve the multi-objective optimization problem.

Despite extensive research, a concept to combine and weight all the objectives and criteria—which is politically approved—lacks in practice. For that, more research is needed to test multi-objective approaches on a variety of networks and traffic conditions and to potentially find a good composite measure (of mobility, safety, and environment) that would enable good quality single-objective optimizations.

Methods of Designing a Signal Plan

Methods of signal plan designing, that is, obtaining values of different components of signal plan can be in general, divided into four types based on their core steps and the philosophy.

1. Critical-movement-based method with the NEMA ring-barrier constraint: It is mainly applied in the United States and Canada. Critical phase/ movement pairs are identified according to the sum of phase volumes, and those critical phases must be in one side of the barrier in the same ring. Refer to [Urbanik et al. \(2015\)](#) for more details.
2. Group-based/movement-based method: It is used in Germany, Austria, and Switzerland. It is characterized by calculating intergreen times for all the conflicting flows and determining the stage sequence to minimize the total intergreen times. The purpose of the combination of signal groups in Germany and Austria is to minimize the critical sum of traffic stream volumes. Conversely, in other types of methods, the stage structure and sequence are usually decided before calculating intergreen times.
3. Critical-movement-based method without the NEMA ring-barrier constraint: It is adopted in Australia and New Zealand. Two major tools, that is, the critical movement search table and the critical movement search diagram, are used to identify critical movements.
4. Stage-based method: It prevails in the United Kingdom, France, Turkey, Japan, China, India, South Korea, Qatar, and UAE. Stages are usually predefined according to intersection geometry and traffic volumes. Webster's method is mostly utilized with equal v/c ratios for all stages. Furthermore, signal timing plans are adjusted based on the requirements of the minimum green times for pedestrians and vehicles

Refer to [Tang et al. \(2019\)](#) for a comparative explanation of abovementioned methods. For more details on standard practices of calculating signal parameters, refer to [Akcelik \(1981\)](#); [FHWA \(2008\)](#). As suggested in [Tang et al. \(2019\)](#), the selection of the signal designing method depends on multiple factors, such as signal control objectives, functionalities of signal controllers, individual needs of public transport priority or signal coordination, traffic flow characteristics, and intersection geometry.

Traffic Signal Control Modes

There are various traffic signal control modes, which differ in the degree of variability of different control parameters (i.e., cycle time, stage number, stage sequence, green times, offset time). These control modes are listed below:

1. Fixed-time control: in this mode, none of these parameters in the signal plan is flexible. Signal plans are designed offline for various demands using historical traffic data. Suitable signal plans are selected and activated for a specific time of the day, which is referred to as the time-dependent (or time-of-day) signal control.
2. Actuated control: in this mode, at least one of the parameters in the signal program is actuated according to the current situation (e.g., green time adaptation based on traffic volume detection). Following two options are possible:
 - a. Semi actuated control: generally minor movements are actuated, which allows for an indefinite extension of green time for major movements until minor phase demand is actuated
 - b. Fully actuated traffic control: all movements (phases) are actuated, which allows for variation of phase sequence and duration depending on traffic demands

Refer to [Ni \(2020\)](#) for more details on vehicle actuation at a signalized intersection.
3. Traffic responsive plan selection: based on detector data returned from the field, traffic responsive algorithms select a preconfigured (i.e., predetermined) signal timing plan from a library of plans.
4. Real-time or adaptive control: In this mode, real-time detection data and algorithms are used to adjust signal-timing parameters for current conditions. Unlike traffic responsive plan selection systems, which use predetermined timing plans, in this mode, the system can adjust various timing parameters (within certain constraints) based on what the traffic requires.

Actuated or adaptive control is more common in most of the economically developed countries, including the United States, Canada, Germany, Austria, the United Kingdom, France, Switzerland, Australia, New Zealand, and Japan. Whereas, economically developing countries such as India, China, South Korea majorly rely on Fixed time control ([Tang et al., 2019](#)). There are various tools available to design offline fixed time control such as TRANSYT ([Robertson, 1969](#)), TRNASYT-7f ([Wallace et al., 1984](#)), SIDRA intersection ([Akcelik Associates Pty. Ltd., 1984](#)) etc. Due to rapid development of detection and computer technologies, most of the new generation signal controllers such as controllers by Siemens, Econolite, Swarco, Tyco, Nippon, etc. offer actuation.

Adaptive traffic control systems (ATCS) have been in continuous use since the 1980s. The first successes of ATCS include SCATS ([Hunt et al., 1981](#)) and SCOOT ([Lowrie, 1982](#)), which were soon followed by an FHWA initiative ([Tarnoff and Gartner, 1993](#)) to develop ATCSs in the United States. ATCSs currently in practice include SCATS, SCOOT, Centrac, ATMS, BALANCE, TACTICS, and VS-PLUS, etc. For more information on field experiences with ATCSs systems, refer to [Stevanovic \(2010\)](#).

Though a variety of centralized adaptive control systems have been developed and implemented in several countries, their practical effectiveness and cost-benefit have been argued over for a long time in industry and academia. These systems are generally considered to be capable of handling highly fluctuated traffic flow at the network level, mainly relying on good-quality traffic detectors and experienced engineers. However, due to the failure of traffic detectors and lack of experienced and knowledgeable people, as well as complex dynamics of traffic flow, the capabilities and functionalities of these systems cannot be fully utilized in many cases. Thus generally, their practical performance has not yet been compelling.

On the other hand, many academics and practitioners believe that well-designed fixed-time signal control, together with well-defined corridor coordination, is a good alternative in terms of cost and benefit, given limited resources for installing advanced signal controllers and systems as well as hiring experienced engineers for signal timing design and maintenance. Besides, the isolated actuated signal control with simple control logic is also considered as an efficient means for rural intersections. In some countries, such as the United States and Germany, actuated-coordination control has also proved to be quite useful. Researchers (Yin, 2008; Zhang and Yin, 2008; Zhang et al., 2010) have also proposed concept of robust signal plan to improve the performance of fixed time signals under varying demand. The signal plan that minimizes cost associated with different demand scenarios and whose performance is stable under different realizations of traffic volumes is called robust plan. The signal plan producing the optimal value of the objective functions such as total delay, total throughput etc. is known as an efficient signal plan for a given demand. On the other hand, robustness is a measure of deviation in the performance of a signal plan across various traffic demands. Given the conflicting nature of efficiency and robustness of signal control, a trade-off would be inevitable to make. Objective of robust signal plan is to achieve the reasonable trade-off between efficiency and robustness to achieve satisfactory performance of signal plan under varying demand.

Performance Evaluation

Performance evaluation is fundamental for continuous monitoring and improvement of signal timing plans at signalized intersections. Comprehensive and accurate assessment can help to diagnose signal control problems and providing insights for improvement. Thus, it is not only essential for the signal plan designing stage but also crucial for the operation and maintenance stage. From the viewpoint of cost-benefit, efficient monitoring and improvement of existing signal timing plans are sometimes more effective than using advanced control systems and devices.

Performance indicators for the evaluation of signalized intersections include control delay, capacity, degree of saturation, queue length, number of stops, travel time, number of traffic accidents or conflicts, fuel consumption, and so on. Though average control delay is widely used for determining LOS, the multicriteria and multimodal impact assessment has gained increasing concerns, which simultaneously accounts for the safety, efficiency, environment, and energy of multiple traffic modes. For instance, control delay per person might be a good integrated indicator in the context of multimodal operations, as it can account for the number of people accommodated by each type of vehicle. On the other hand, performance indicators should be appropriately selected based on signal control objectives, as too many indicators do not necessarily contribute to improvement. As discussed in Goals of designing signal plans, the importance of various performance indicators vary under different traffic circumstances.

In the past, the management of traffic signal systems was evaluated by labour-intensive processes, such as floating-car studies. In the mid-2000s, the concept of “high-resolution data” took shape (Smaglik et al., 2007a; Smaglik et al., 2007b; Liu and Ma, 2009). These studies required the real-time traffic states at individual detectors, which needed to be cross-referenced against the active signal state during each moment of operation. Based on such data, researchers soon developed Automated Traffic Signal Performance Measures (ATSPM) (Day and Bullock, 2011; Gettman et al., 2012; Wu and Liu, 2014). ATSPM are control-agnostic, discrete event-based performance measures for analyzing the actual operation of traffic signal systems, applicable within any signal system and for all types of operations (Day et al., 2014). ATSPM helps in automizing the process of performance evaluation and finding opportunities for improvement using real time data from traffic sensors and signal controller (Day et al., 2016). Soon many signal vendors started implementing high-resolution data collection in their controller products, which led to the development of software to deliver ATSPM to the user (UDOT, 2020).

The various sensors used to collect real-time traffic data for performance evaluation and operation of ATCSs are summarized below (Stevanovic, 2010):

- Inductive loop detectors: these detectors are classified based on their position at intersection approach such as stop-line, upstream mid-block, upstream far side.
- Radar detectors
- Video detection

These sensors are used to measure or estimate various traffic flow characteristics such as vehicle count, speed, occupancy (i.e., percentage of time detector is occupied), queue length etc. Since 2006, automatic vehicle identification (AVI) data in the form of Bluetooth MAC address matching emerged (Wasson et al., 2008). Thus, in the past few years, the raw vehicle position data has been applied to evaluate and adjust signal timing (Quayle et al., 2010; Remias et al., 2013; Sharifi et al., 2017). Future development of similar data sources and performance measures based on that data is a current research trend as discussed in the following section.

Advances Due to Connected and Automated Vehicle Technology

New wireless communication and computational technologies, such as connected and automated vehicles (CAVs) have inspired new methods of controlling traffic. The benefits of introducing CAVs include but not limited to crash reduction/elimination, travel time reduction, energy efficiency improvement, and others. Current research in the area of traffic control focus on achieving the following goals with the aid of CAVs:

- CAVs data can be used to improve the estimation accuracy of the performance indicators (Wan et al., 2016; Rompis et al., 2018; Xie et al., 2018)
- Better signal plans can be designed, as the arrivals of vehicles could be better predicted in advance (Goodall et al., 2013; Wu et al., 2015; Younes and Boukerche, 2016; Liang et al., 2018)
- Drivers and fully automated vehicles could better adapt their trajectories to cooperate with signal timing to reduce overall congestion and fuel consumption in urban areas (Katsaros et al., 2011; Li et al., 2012; Ubiergo and Jin, 2016; Tang et al., 2018)
- With CAVs, information between signals and individual vehicles can be exchanged in real-time, which can be used to simultaneously guide the vehicle's trajectory and plan better signal control. Such simultaneous planning is referred to as Signal vehicle coupled control (SVCC) (Xu et al., 2017; Yu et al., 2018)
- Recent studies (Hu et al., 2016; Wu et al., 2016; Wu et al., 2018) utilized CAVs to build efficient algorithms for transit priority control methods. CAVs provide more accurate and richer data for the control system, which help to generate an optimal solution to reduce the overall delay.

With this new technology, come new challenges such as variation in penetration rate and level of automation of CAVs, limited field data to test the developed methods, reliability of wireless communication and cyber security issues. Besides, technical and organizational obstacles also exist. The roles, responsibilities and business models of the different stakeholders are not clearly specified yet. From the technical point of view, since the currently installed infrastructure is expensive and partially aged, researchers need to think about simple ways for upgrading to connected environments. Thus, while the benefits of the CAVs are evident, there are still obstacles on the way to a large-scale functionally homogeneous CAV system deployment.

Glossary

Movement Classified motorized and pedestrian traffic streams at an intersection according to direction, lane and right-of-way, etc.

Phase The part of the signal cycle allocated to any combinations of traffic movements receiving the right-of-way simultaneously during one or more intervals.

Signal group A group of one or more traffic flows which receive identical signal light indications.

Stage A part of the cycle during which a particular set of compatible streams receives green while all others have to wait.

Protected phase A separate phase for protected movement with no conflicting traffic flows.

Permitted phase A timing treatment allowing two or more conflicting movements to pass concurrently.

Lost time The time between signal phases during which an intersection is not used by any traffic.

Crosswalk A marked area for pedestrians to cross the street at an intersection or designated midblock location.

Definition of Protected Phase

- **Phase, signal group and stage** A traffic signal phase, or a **phase** for short, is a timing process within the signal controller, that facilitates serving one or more movements at the same time for one or more modes of users. A **signal group** refers to a group of one or more traffic flows which always receive identical signal light indications. A **stage** is a part of the cycle during which a particular set of compatible streams receives green while all others have to wait (Tang et al., 2019). Fig. 1 provides a description for these three terms in the scope of an intersection for better understanding. Note that the term “phase” used here should not be confused with the term “NEMA phase” widely used in North America, which is a green time interval accommodating only one movement, that is, a through movement or a left-turn movement (FHWA, 2009; Transportation Research Board, 2010).
- **Protected phase** Also known as “protected-only phase”, **protected phase** refers to providing a separate phase for protected movements with no conflicting traffic flows. In contrast, **permitted phase** (also known as “permitted-only phase”, “permissive-only phase”) refers to a timing treatment allowing two or more conflicting movements to pass concurrently. As a compromise, **protected/permitted phase** is a compound phase that displays the permitted phase after the protected phase. While, **permitted/protected phase** is a compound phase that displays the permitted phase before the protected phase. Note that these three terms are more commonly used for motor vehicles, while specific designations do exist for protected phase of public transport and non-motorized traffic, such as exclusive phase, pedestrian scramble and so on.

Types of Protected Phase

To avoid confusion, in the following text the protected phases for motor vehicles are introduced in the context of **right-hand traffic**.

- **Protected left-turn phase (motor vehicles) and its displays**
Traffic signal phasing that provides an exclusive phase for left turns and prohibits opposing through movements and pedestrian crossings is known as a **protected left turn phase**. There are two types of protected left-turn phases according to phase sequence, that is, leading left turn and lagging left turn. A leading left turn allows the green phase of left-turn movements ahead of the green phase of through movements, while a lagging left turn places the green phase of the left turn after the green phase of through movements.

Figure 1 Illustration of phase, signal group and stage.

As shown in [Fig. 2](#), the left turn green arrow light is widely used as the exclusive display of left turn protected phase. Despite different signal head arrangements in various countries, green arrow light is used to direct vehicles to turn in the direction that the arrow indicates, when operated together with signal lights of other phases ([Tang et al., 2019](#)).

- **Protected right-turn phase (motor vehicles) and its displays** Traffic signal phasing that provides an exclusive phase for right turns and prohibits conflicting pedestrian crossings is known as a protected right turn. As shown in [Fig. 3](#), a right-turn green arrow signal indication is displayed under the protected right-turn phase ([Tang et al., 2019](#)).
- **Protected public transport phase and its displays** Traffic signal phasing that provides an exclusive phase for public transport (like BRT, LRT) and prohibits private vehicle movements and pedestrian crossings is known as a protected public transport phase. Examples of signal displays for the protected public transport phase in different countries are given in [Fig. 4](#). Note that the signal displays may be varied for different kinds of public transport in different countries, yet with the same function to indicate when to stop or go for public traffic ([FGSV, 2015](#); [JSTE, 2006](#); [The Ministry of Public Security of the People's Republic of China, 2015](#); [Urbanik et al., 2015](#)).
- **Protected pedestrian phase and its displays** Traffic signal phasing that provides an exclusive phase for pedestrians and prohibits conflicting motor vehicle movements is known as a protected pedestrian phase. Generally, protected pedestrian phase can be operated in pair at an intersection for pedestrians of both sidewalks along a road, together with parallel through phases for motor vehicles. Examples of signal displays for the protected pedestrian phase in some countries are shown in [Fig. 5](#) ([JSTE, 2006](#); [The Ministry of Public Security of the People's Republic of China, 2015](#); [Urbanik et al., 2015](#); [FGSV, 2015](#)).

Figure 3 Examples of signal displays for protected right-turn phase: (A) United States, (B) Germany, (C) China, and (D) Japan.

- **Protected bicycle phase and its displays** Traffic signal phasing that provides an exclusive phase for bicycles and prohibits conflicting motor vehicle movements is known as a protected bicycle phase. Generally, bicycles share the same right-of-way as pedestrians, thus the same signal phase and even signal display. Examples of signal displays peculiar to bicycles implemented in some countries are shown in Fig. 6, which are sometimes also used to indicate exclusive right-of-way for both pedestrians and bicycles.

When and Where to Implement a Protected Phase

- **Protected left-turn phase**

When and where to implement a protected left-turn phase as well as the selection of its protection types (i.e., protected/permissive, permitted/protected, or protected only) must be determined before signal timing calculations. Generally, the protected left-turn phase for motor vehicles should be considered if any of the following conditions is satisfied (FSV, 1998; National Police Agency of Japan, 2015; Rodegerdts et al., 2004; The Ministry of Public Security of the People's Republic of China, 2016).

1. There is more than one exclusive left-turn lanes, or more than one opposite through lanes;
2. The left-turn volume is high, or the conflicting traffic volumes in the opposite through direction are high. For example, the left turn has a demand in excess of 240 veh/h, which is only be used for planning applications;
3. There are more than one streams conflicting with the left-turn movements;
4. The speed of the opposite flow is relatively high;
5. The left-turn lane is placed on right or a shared U-turn and left-turn lane exists

To implement a protected left-turn phase, many other factors should also be considered, including accident frequency, field observations, and conditions that may exist outside of the analysis period.

Figure 4 Examples of signal displays for protected public transport phase: (A) United States, (B) Germany, (C) China, and (D) Australia.

- **Protected right-turn phase**

In many cases, right-turning vehicles share a lane with through vehicles and should yield to crossing pedestrians and cyclists in many countries such as United States, Germany, and China. When the exclusive right-turn lane is available, implementation of protected right-turn phase may be considered. More in detail, the protected right-turn phase for motor vehicles should be considered if any of the following conditions is satisfied (FSV, 1998b; Rodegerdts et al., 2004).

1. Parallel pedestrian volumes are high and safety considerations predominate.
2. Right-turn traffic volumes are high or many conflicts with parallel pedestrians or cyclists occur and cannot be mitigated by other means;
3. Trams have separate through tracks on the right;
4. The right-turn traffic demand and the left-turn traffic demand at the crossing road are balanced.

Protected Public Transport Phase

Protected phase for public transport can be considered only when an exclusive lane bus lane is available. Factors like the number of bus routes passing the intersection and traffic demand of private vehicles should be taken into account to improve the efficiency of public transit without causing severe delay of social vehicles of other phases.

- **Protected pedestrian phase**

Generally, pedestrians enjoy priority when crossing the intersection permitted with turning vehicles, so the pedestrian movement can be regarded as protected. In case that the protection for pedestrian requires to be more mandatory, protected phase exclusive for pedestrians should be considered, and the following conditions can be used as a reference ([FSV, 1998](#); [National Police Agency of Japan, 2015](#); [Rodegerdts et al., 2004](#); [The Ministry of Public Security of the People's Republic of China, 2016](#)).

1. The pedestrian demand is high and the impact of the conflict between pedestrians and turning vehicles are expected to be significant;
2. Delay for vehicular turning traffic is excessive due to the heavy pedestrian traffic;
3. There are a large number of vehicle-pedestrian conflicts involving all movements;
4. Multiphase signal indications (as with split-phase timing) would tend to confuse or cause conflicts with pedestrians using a crosswalk guided only by vehicular signal indications;
5. At an established school crossing at any signalized location;
6. A protected pedestrian phase for all directions can be used at intersections with diagonal pedestrian-crossing lane markings. Such exclusive pedestrian signal phase allows pedestrians to cross in all directions at the same time, including diagonally. Vehicle signals are red on all approaches of the intersection during the exclusive pedestrian signal phase. It is sometimes called a "barn dance" or "pedestrian scramble," whose objective is to reduce vehicle turning conflicts, decrease walking distance, and make intersections more pedestrian-friendly.
7. Under some special situations of unconventional intersection geometric design, no vehicular signal indications are visible to pedestrians, or the vehicular signal indications that are visible to pedestrians starting or continuing a crossing provide insufficient guidance for them to decide when it is reasonably safe to cross, such as on one-way streets, at T-intersections, or midblock crossing for links where neighboring intersections are far away for pedestrians to access.

- **Protected bicycle phase**

Generally, bicycle movement operate concurrently with pedestrian movement when passing the crosswalk at the intersections. Non-motor vehicles should yield to pedestrians when they have conflicts on the crosswalk while turning motor vehicles should yield to both the bicycles and pedestrians crossing the intersections. Thus, the guidelines for setting protected pedestrian phase can also be applied to protected bicycle phase when an exclusive lane for bicycles is available. Two additional conditions are listed as follows to provide specific suggestions for protected bicycle phase ([Urbanik et al., 2015](#)).

1. For two-phase intersections, exclusive signals or exclusive phases should be set up for left-turn non-motor vehicles if the average left-turn flow rate during the red interval is relatively heavy. Alternatively, other ways of street crossing organization for non-motor vehicles should be adopted;
2. For four-phase intersections, non-motor vehicle exclusive signals should be set up when the green interval needed by the non-motor vehicles is obviously larger than the motor vehicles in the parallel direction. And an "early break" mode should be adopted by the non-motor signals.

Operational and Safety Performance of Protected Phase

- **Operational performance**

According to the signal timing design procedure, the lost time will be a function of the cycle length and the number of phases. Thus, from the perspective of operational performance, the protected phase directly relates to the delay of users passing the intersection.

For protected turning phases of motorized traffic, protected-only phasing can improve capacity for the protected movements in many cases. However, by adding a protected left-turn phase, the cycle length would be increased and the proportion of green time for critical movements would be decreased. This change in the timing would lead to an increase in the number of vehicle stops for critical movements.

Regarding protected phase for non-motorized traffic, pedestrians and bicycles usually have more crossing opportunities and shorter waits, at the same time increasing vehicular capacity during other phases as conflicting non-motorized traffic is removed. However, an exclusive phase may increase the overall cycle length of the intersection, thus increasing delay for all users.

- **Safety performance**

Usually, treatments can only be expected to be successful when applied to a particular target group of collisions. From this perspective, the installation of protected phasing on one movement should substantially reduce conflicts or collisions involving that particular movement.

For right-hand traffic, left turns are widely recognized as the movement with the highest risk at signalized intersections. Collision types that would particularly benefit from a protected left-turn phase are rear-end and left-turn collisions. Provision of a left-turn lane in conjunction with protected left-turn phasing would appear to provide the most benefit of safety.

Substantial analyses have been done for the safety performance of protected phases of motor vehicles, leading to the following quantitative conclusions.

1. A study of Institute of Transportation Engineers (ITE) of the USA in 2004 indicated that employing split phasing could reduce crashes by 25% (Gan et al., 2005).
2. A study published in 2005 showed a 17% reduction in left-turn crashes with the use of a protected/permissive left-turn phase, and left-turn side-impact crashes was decreased by up to 25% (Lyon et al., 2005).
3. A report in 2008 evaluated crashes involving at least one left-turning vehicle on the treated roadway. Where fully protected phasing was added, left-turn crashes were virtually eliminated, but there was very little change in total crashes (Srinivasan et al., 2008).
4. One study of National Cooperative Highway Research Program (NCHRP) of the USA released in 2004 concluded that left-turn crashes could be reduced by 16% and right-angle crashes by 19% when a protected left-turn phase was provided (Antonucci, 2004).
5. An analysis conducted in 2018 indicated the installation of protected or protected/permissive left-turn phasing could be beneficial in reducing pedestrian crashes at sites with pedestrian-crossing volumes at or exceeding 5500 per day. The protected left-turn phasing evaluation used data from 27 treated sites in Chicago, 7 treated sites in NYC, and 114 treated sites in Toronto. The protected left turn phasing treatment also resulted in decreases of vehicle-vehicle injury crashes by 5% (FHWA, 2018).

At the intersection level, protected phase tends to increase the total number of conflicts, which can result from the following factors.

1. The increase in conflicts comes primarily from rear-end crashes and, under higher flows, from lane-changing maneuvers. As the proportion of green time for through phases is decreased, increasing number of vehicle stops which correlate with the number of rear-end crashes may lead to higher rear-end conflicts.
2. With a greater proportion of vehicles arriving to a standing or dispersing queue, there is an increased tendency of drivers to change to a lane with a shorter queue, despite all lanes having stopped traffic.
3. Vehicle-pedestrian crashes may increase at low pedestrian volumes, as pedestrians may not obey the “do not walk” signal during the protected left-turn phase. Besides, left-turning vehicles are turning left at too high a rate of speed immediately after their protected phase is over and pedestrians begin to cross, thus increasing the probability of vehicle-pedestrian crashes.

Thus, the effect of timing changes and driver behavior should be carefully evaluated before applying protected phase.

Regarding the protected phase of non-motorized traffic, it is noted that the safety benefits of protected-right phase are also covered due to the same starting points. Exclusive right-of-way makes it impossible for the interaction between motorized traffic and non-motorized traffic, thus fundamentally preventing the occurrence of vehicle-pedestrian crashes. Some findings are listed as follows to show the safety performance of protected phase for non-motorized traffic.

1. A paper in 2001 showed that using exclusive pedestrian intervals that stop traffic in all directions had been shown to reduce pedestrian crashes by 50 percent in some locations (i.e., downtown locations with heavy pedestrian volumes and low vehicle speeds and volumes) (Zegeer and Seiderman, 2001).
2. Using the data of all reportable crashes in the five boroughs of New York City in the USA from 1989 to 2008, a study published in 2012 found a 43% reduction in pedestrian crashes from changing the signal phasing from permissive only to protected/permissive or protected only (Bonneseon et al., 2012).
3. A report in 2014 showed that a 47% reduction in pedestrian crashes due to the protected pedestrian phase was found through the comparison of 30 treatment intersections and 493 untreated intersections in New York City in the USA through analysis of a 7-year period covering before and after period (Chen et al., 2014).
4. From data of 1297 signalized intersections involving a total of 2081 pedestrian crashes in 15 U.S. cities, a paper of 2014 showed that exclusive timing was associated with about half of the pedestrian crashes compared with concurrent timing or traffic signals with no pedestrian signals at locations with pedestrian volumes of more than 1200 people/day (Mead et al., 2014).

Another issue concerning the protected non-motorized phase is the utilization of the phase and the compliance of users. Unless a system more heavily penalizes motorists, non-motorized traffic will often have to wait a long time for their exclusive phase. As a result, many pedestrians or bicycles will simply choose to ignore the signal and cross when a gap in traffic occurs.

Summary

This article sheds light on the definition, category, and implementation of protected phase. As a signal treatment, protected phase is to provide exclusive spatial and temporal resources for a specific movement. Though traffic demand and conflictive degree are the main determinants of whether to adopt protected phase, other factors like intersection configuration, field observations of accident experience and sight distance condition also influence the choice of phasing option. For the protected movement, protected phase is the most effective way to improve its safety and progression efficiency, though it may seem kind of simple and crude to some extent. Considering the potential negative effect on the other movements, practitioners should try their best to balance the benefit and cost of applying protected phase through comprehensive actions from data gathering stage, phasing design, public education to field implementation.

Definition of Permitted Phase

Phase, Signal Group, and Stage

- A traffic signal phase, or a **phase** for short, is a timing process within the signal controller that facilitates serving one or more movements at the same time for one or more modes of users. A **signal group** refers to a group of one or more traffic flows which always receive identical signal light indications. A **stage** is a part of the cycle during which a particular set of compatible streams receives green while all others have to wait (Tang et al., 2019). Fig. 1 provides a description for these three terms in the scope of an intersection for better understanding. Note that the term “phase” used here should not be confused with the term “NEMA phase” widely used in North America, which is a green time interval accommodating only one movement, that is, a through movement or a left-turn movement (Transportation Research Board, 2010).
- Permitted phase **Permitted phase** (also known as permissive phase, permitted-only phase or permissive-only phase) is a kind of phase that gives proceeding permission to certain movements during a time in the cycle when the movement does not have the priority. And corresponding road users are going to proceed when there are available gaps in the conflicting flow after yielding to them. In contrast, **protected phase** (also known as protected-only phase) refers to providing a separate phase for protected movements with no conflicting traffic flows. And corresponding road users can proceed safely without any conflicts. As a compromise, **protected/permitted phase** is a compound phase that displays the permitted phase after the protected phase, while **permitted/protected phase** is a compound phase that displays the permitted phase before the protected phase. Note that these terms are more commonly used for motor vehicles, and could rarely be seen for nonmotorized traffic. Therefore, this chapter mainly discussed the permitted phase for motor vehicles.

Types of Permitted Phase

For signalized intersections, there are mainly two kinds of permitted phase according to the type of turning, namely permitted left-turn phase and permitted right-turn phase. To avoid confusion, in the following text the permitted phases for motor vehicles are introduced in the background of **right-hand traffic**.

- **Permitted left-turn phase and its displays** Permitted left-turn phase permits the left-turn vehicles of subjective approach to proceed after yielding to conflicting vehicular (opposing through vehicles) and pedestrians (parallel pedestrians) traffic before completing the turn. Left-turn vehicles could proceed when there are acceptable gaps between two consecutive conflicting users' movements. Typical signal indications of permitted left-turn movement across countries are shown in Fig. 2. Permitted Left-turns are often made on a circular green signal indication, a flashing left-turn yellow arrow signal indication, or a flashing left-turn red arrow signal indication after yielding to pedestrians or opposing traffic. During a permitted left-turn movement, the signal faces for through traffic on the opposing approach simultaneously display green or steady yellow signal indications (Tang et al., 2019).
- **Permitted right-turn phase and its displays** In general, the right-turn movement is served concurrently with adjacent through movement (i.e., by default permitted). Permitted right-turn phase permits the right-turn vehicles of subjective approach to proceed after yielding to conflicting pedestrians (parallel pedestrians) traffic before completing the turn. Right-turn vehicles could proceed when there are acceptable gaps in the pedestrian flows. Typical signal indications of permitted right-turn movement across countries are shown in Fig. 3. Permitted right-turns are often made on a circular green signal indication, a flashing right-turn yellow arrow signal indication, or a flashing right-turn red arrow signal indication after yielding to conflicting pedestrians (Tang et al., 2019).

Figure 1 Sketch map for phase, signal group and stage.

When and Where to Implement a Permitted Phase

- Permitted left-turn phase** The type of signal phasing used for a left-turn movement directly affects safety and operational performance of the turn. In general, less-restrictive phasing schemes are preferable where appropriate because they result in lower delay to all users of the intersection (Koonce and Rodegerdts, 2008). A variety of guidelines exist that indicate conditions where the benefits of left-turn phases typically outweigh its adverse impact to overall intersection operation (Agent et al., 1995; Upchurch, 1986). Many of these guidelines indicate that a left-turn phase can be justified based on consideration of several factors that ultimately tie back to the operational or safety benefits derived from the phase. These factors mainly include: left-turn and opposing through volumes, number of opposing through lanes, cycle length, speed of opposing traffic, sight distance, and crash history. Generally, protected or semi-protected left-turn phasing (protected-permitted, permitted-protected, or protected only) should be considered if any one of the following criteria is satisfied, and permitted left-turn phasing may be considered at sites that do not satisfy any of these criteria (Rodegerdts et al., 2004):

1. A minimum of two left-turning vehicles per cycle and the product of opposing and left-turn hourly volumes exceeds certain value (45,000 per opposing lane).
2. The left-turning movement crosses three or more lanes of opposing through traffic.

(A)

(B)

(C)

(D)

Figure 3 Examples of permitted right-turn phase display: (A) United States, (B) Germany, (C) China, and (D) Australia.

3. The posted speed of opposing traffic exceeds 70 km/h.
4. Recent crash history for a 12-month period indicates 5 or more left-turn collisions that could be prevented by the installation of left-turn signals.
5. Sight distances to oncoming traffic are less than the standard minimum distances.

6. The intersection has unusual geometric configurations, such as five legs, when an analysis indicates that left-turn or other special traffic signal phases would be appropriate to provide positive direction to the motorist.
7. An opposing left-turn approach has a left-turn signal or meets one or more of the criteria here.

- **Permitted right-turn phase**In many countries, such as United States, Germany, and China, right-turning vehicles commonly share a lane with through vehicles and are realized together with the through vehicles, pedestrians and cyclists at the intersection. Therefore, right-turn phasing would by default be permitted phase unless the following conditions are satisfied:

1. The subject right-turn movement is served by one or more exclusive right-turn lanes.
2. The right-turn volume is high (e.g., 300 veh/h or more).
3. A left-turn phase is provided for the complementary left-turn movement.
4. U-turns from the complementary left-turn are prohibited.

If the aforementioned conditions are satisfied, then the appropriate operational mode can be determined. If the through movement phase for the subject intersection approach serves a pedestrian movement, then the right-turn phasing should operate in the protected-permitted mode, and the permitted operation would occur during adjacent through movement phase. If the through movement phase for the subject intersection approach does not serve a pedestrian movement, then the right-turn phasing should operate in the protected-only mode during both the adjacent through movement phase and the complementary left-turn phase (left-turn phase of the neighboring or intersecting approach).

Operational and Safety Performance of Permitted Phase

- **Operational performance**

Permitted phase provides the most efficient green time allocation to users within intersection, but the efficiency is dependent on the availability of gaps in the conflicting traffic. From the perspective of traffic operations, provision of permitted left-turns during the through green will always be beneficial regardless of the type of signal control or left-turn sequence pattern. Only in situations where safety concerns are an overwhelming influence should permitted left turns be prohibited.

- Trial for four intersections in 1979 demonstrated that the use of permitted-turn phasing resulted in a 50% reduction in left-turn delay and a 24% reduction in total delay compared to exclusive left-turn phasing (protected only phase). Meanwhile, questionnaire responses showed that over 90% of drivers were in favor of this type of signal ([Agent, 1981](#)).
- Study in 1981 found that permitted-only left-turn phase could reduce left-turn delays by approximately 30% and as much as 50%. Left-turn delays versus left-turn volumes were found to have a linear relationship up to capacity conditions ([Rocciola, 1981](#)).
- A study in 1995 included 264 intersections and data obtained from 518 approaches. These intersections were scattered across the United States with approaches included in 52 counties. At these intersections, protected-only left-turn phasing resulted in high left-turn delays while permitted phasing can reduce these delays. For approaches with one opposing lane, the use of permitted or protected/permitted left-turn phasing produced similar left-turn delays; for approaches with two opposing lanes, protected/permitted phasing produced lower delays than permitted. Moreover, the study pointed out that the desired left-turn phasing for both one and two-lane approaches is protected/permitted phase since it produces similar delays as permitted while it provides some level of safety for left-turning vehicles, and protected-only left-turn phasing should be considered only for locations with a high number of left-turn accidents or where there is a high left-turn accident potential ([Agent et al., 1995](#)).
- For permitted right-turns, right-turn-on-reds (RTORs) are developed as a fuel- and time-saving measure, vehicles could proceed to turn right without having to wait for green signal. In the United States, western states have allowed it for more than 50 years, and eastern states amended their traffic laws to allow it in the 1970s as a fuel-saving measure in response to motor fuel shortages in 1973. And all states have allowed right turns on red since 1980.

- **Safety performance**

Permitted phase can have an adverse effect on safety in some situations, such as applying permitted left-turn phase when the left-turning vehicles' view of conflicting traffic is restricted or when adequate gaps in traffic are not present.

- Trial for four intersections in 1979 demonstrated that the permitted left-turn phasing resulted in an increase in left-turn accidents. However, other accident types, such as rear-end accidents, did not increase. The number of left-turn accidents decreased as drivers became more familiar with the signals ([Agent, 1981](#)).
- Study in 1981 found that traffic conflicts were higher for permitted phase than protected phase while accident experience were not increased significantly, and the critical number of accidents at an permitted only phase has been determined to be 10 per year ([Rocciola, 1981](#)).
- For the study in 1995, considering all approaches, 69% had an average of 0.5 left-turn accidents per year or less. This percentage was 93% for protected-only phasing locations compared to 40% for protected/permitted phasing and 71% for permitted phasing approaches. Only 8% had an average of over two accidents per year with no protected-only approaches having this

number of accidents. This percentage was 18% for protected/permitted phasing and 7% for permitted phasing approaches. Besides, the average was only 0.20 left-turn accidents per approach per year for approaches with protected-only phasing and increased to 1.32 for protected/permitted phasing and 0.50 for permitted approaches (Agent et al., 1995).

- A surrogate safety assessment indicated that total number of conflicts for permitted left turn is significantly more than that of protected left turn; Protected left turn has less crossing conflicts but more rear-end and lane-change conflicts than permitted left turn. The comparison results for all other safety measures show no distinct safety preference between protected left turn and permitted left turn (Gettman et al., 2008). The following cited references (Gettman et al., 2008) are not included in the reference list. Either include the cited references with complete details in the reference list or delete their citations from the text..
- RTORs can also be detrimental for pedestrians and cyclists. A 1981 US Department of Transportation study determined that the frequency of motor vehicle collisions with bicyclists and pedestrians when the vehicle was turning right increased significantly after the adoption of RTOR. It also demonstrated that estimates of the magnitude of the increases ranged from 43% to 107% for pedestrian accidents and 72% to 123% for bicyclist accidents (Preusser et al., 1982). A 1984 study found that where RTOR was allowed, all right-turning crashes increase by about 23%, pedestrian crashes by about 60%, and bicyclist crashes by about 100% (Zador, 1984). A 1993 study also concluded that RTOR increased crashes for pedestrians and cyclists, by 44% and 59% respectively (Dussault, 1993).

In general, the operational benefits of permitted phase, for both left-turn and right-turn, are proved in early days, great delay reduction had been shown by replacing protected-only phases with permitted phase. The reductions in delay are encouraging toward additional but discriminating use of permitted left-turn phasing. Meanwhile, the accidental potential is indeed increased which limits its use to intersections that has suffered from accident problem. More recently, with increasing vehicles on the road, researchers have also increasingly investigated the gap acceptance theories, and the usage of left-turn permitted-only phase is decreasing for safety considerations, while no-right-turn-on-red has also been attempted in certain intersections to protect pedestrians and cyclists. Protected/permitted left-turns and prohibited/permitted right-turns are becoming potential alternatives.

Summary

This article focuses on the definition, types, implementations as well as operational and safety performances of permitted phase. As a widely-used signal treatment, permitted phase provides certain road users of permission to proceed without right-of-way, mainly including left-turn and right-turn motor vehicles. It is developed as an effective measure to decrease the vehicle delays and increase capacity of intersections only when safety issues do not occur. However, increased conflicts are also bounded for permitted phase and so as accidental potentials. Though several investigations demonstrated a decreased rear-end crashes and insignificant change in accidents, the implementation of permitted phases shall be cautious and take varied factors into consideration.

Introduction

In recent decades, light rail transport systems and trams have drawn the attention of traffic engineers and urban planners due to their advantages as a popular mode of public transport. The light rail transport is more accessible than heavy rail transport as they share the road with other road users. Tram tracks are usually located in the middle of the streets. Thus, the interaction between trams and different modes of transport is always a challenge for traffic engineers and safety experts, especially at busy intersections. This problem is more common when the allocated space for the right-turn traffic is limited. While waiting for a safe gap in opposing traffic to make a turn, the right-turn traffic can block the through the movement of trams. Hook turns have been introduced as a novel approach to minimize the impact of right-turn traffic on not only the tram movements but also the other modes of transportation. Hook turns have been implemented to buses, bicycles and motorcycles to improve their safety.

In this article, the history of hook turns, and the background of hook turn implementation will be described first. Then, by providing examples, different types of hook turns in metropolitan Melbourne will be presented followed up by the examples of implementing hook turns for bicycles and motorcycles. It is followed by investigating the impact of hook turns on traffic safety. Afterwards, different illustrations of the traffic management improvements resulted from the implementation of the hook turns will be presented. Then, the limitations and disadvantages of hook turns will be discussed. Finally, the summary of the article will be presented.

Background

Hook turn is a traffic management approach that is originally implemented in the Melbourne Central Business District (CBD) more than 60 years ago. The primary purpose of introducing this approach was to clear the CBD road network for the movement of trams. Tram system in Melbourne is one of the most crucial components of the public transport system in inner Melbourne. Trams are the second most popular mode of public transport in metropolitan Melbourne and comprise the highest passenger demand after the heavy rail system.

The Melbourne tram network is one of the largest tram networks in the world and consists of 250 kilometers of double tracks (25 routes and more than 1,700 stops). In 2019, more than 205 million trips were served by the Melbourne tram network. **Figure 1** shows the map of the Melbourne tram network.

At present, the Melbourne road network comprises 49 hook turns (Currie and Reynolds, 2011; Falamarzi et al., 2018). **Figure 2** shows an aerial view of an intersection with a hook turn in Melbourne CBD. It must be noted that hook turns are also used by cyclists and motorcyclists at intersections to make a right turn. Hook turn as a safe approach may help these road users avoid crossing multiple lanes for reaching the middle of the road and the right turn lane.

Hook turns are not limited to Melbourne's tram network. Some bus routes have adopted the hook turn in Australia and worldwide. Hook turns have been introduced for buses in Adelaide, Australia (at two intersections), and in Shanghai, China. Hook turns have been used for different road users in Illinois, United States of America, China, and Taiwan (Hounsell and Yap, 2013). The idea behind introducing the hook turn was originated from the conflict between trams and the traffic intending to make right turns at intersections. The right turn traffic can potentially embed the movement of trams while looking for a safe and sufficient gap in opposing traffic. Instead on implementing hook turns, there are two potential solutions to deal with this problem and avoid blocking trams, including (1) restricting the right turn traffic movements, or (2) modifying the traffic signals to accommodate a protected right turn phase and assigning an exclusive traffic signal phase to right turn traffic which means an additional signal phase at the intersections. The second solution brings a significant disadvantage to the trams, as it is imposing

Figure 1 Map of the Melbourne tram network (Yarra Trams, 2020).

Figure 3 Hook turn function in a left-hand traffic context (Currie and Reynolds, 2011).

additional delays to tram systems, and on a broader aspect, reducing the reliability and attractiveness of this mode of public transport. Both solutions result in reducing the capacities of intersections. By using the hook turns, there is no need for extra lanes dedicated for turning vehicles (Currie and Shalaby, 2007).

According to VicRoads Guidelines (VicRoads, 2020), a few steps should be undertaken to safely perform a hook turn (Figure 3). First, vehicles need to approach the hook turn intersection from the far left lane and turn on the vehicle indicator for turning right. Then, the vehicles need to move toward the most left side of the intersection and keep clear of any pedestrian crossings. The right-turning vehicles need to stay stopped and wait until the traffic lights for the road they are planning to turn to, become green.

Different Types of Hook Turns in Melbourne

There are four main types of hook turns implemented in the Melbourne metropolitan area, which have been integrated with tram movements. In Figure 4, typical hook turn designs along with non-hook turn designs are illustrated. In Figure 5, different examples of hook turn implementations in metropolitan Melbourne are illustrated.

Type 1 is related to the typical hook turn implementation within the Melbourne CBD, which includes two traffic lanes, the tram right-of-way and a tram stop or a safety zone stop. The safety zone is located between the through lane and the tram track. Safety zone stops can be either at the same level with the streets or be raised. Both stops are designed for improving the safety of pedestrians boarding or alighting a tram. They can protect pedestrians from the general traffic by a railing. An example of this type of hook turn has been implemented at the intersection of La Trobe Street and Swanston Street in Melbourne CBD.

Type 2 is similar to Type 1 but without a tram stop or traffic island. An example of this type of hook turn has been implemented at the intersection of La Trobe Street and Elizabeth Street in Melbourne CBD.

Figure 4 Different types of hook turns in metropolitan Melbourne (Currie and Reynolds, 2011).

Figure 5 Different types of hook turn implementations (Types 1, 2, 3, and 4) in metropolitan Melbourne, (Google, 2020).

Figure 6 Performing a hook turn at an unsignalised intersection by a cyclist (TMR, 2020).

Type 3 is similar to Type 1 but is used at locations without sufficient space for two lanes on the approach to the intersection. Vehicles still undertake a hook-turn movement, with through vehicles overtaking the right-turning cars on the right within the intersection. An example of this type of hook turn has been implemented at the intersection of Collins Street and William Street in Melbourne CBD.

Type 4 has been implemented on Clarendon Street, a strip shopping center outside the CBD area. This treatment is accompanied by curb-side tram stops.

Hook Turn for Cyclists and Motorcyclists

In addition to cars, bicycles, and motorcycles use hook turns in some countries including Australia, the Netherlands, New Zealand, and Taiwan. In these countries, hook turn as a practical traffic management approach has provided a safe turning movement by reducing the exposure of cyclists and motorcyclists to other vehicles and multi-lane traffic flow. In this section, different examples of the hook turn approach designed for cyclists and motorcyclists are presented.

For instance, in Queensland, Australia, the transport authorities have specified the hook turn rules for cyclists at intersections with and without traffic lights. If the intersection has a traffic light, the right-turning cyclists need to keep to the far left side when approaching the intersection and then stay at the left-hand side of the intersection. They need to wait and give way to through traffic and move forward across the intersection when the road is clear (at unsignalized intersections) or when the signal light turns green (at signalized intersections). The performance of hook turns at an unsignalized intersection has been depicted in [Figure 6](#). In some intersections, a hook turn storage box ([Figure 7](#)) has been implemented. This area provides a safe, dedicated area for right-turning cyclists to stop and wait (TMR, 2020).

Figure 7 Hook turn storage box at the Whiteleigh-Lincoln intersection, Christchurch, New Zealand (Cycling in Christchurch, 2020).

Figure 8 A schematic view of making a left turn at an intersection in British Columbia (ODOT, 2017).

In British Columbia, Canada, where vehicles move on the right side of the road, cyclists have three main methods of performing a left turn maneuver at signalized intersections (Figure 8). In the first method (movement 1), similar to cars, cyclists make a left turn at intersections from the middle of the road and the far left side of the intersection. In this method, cyclists and other vehicles merge while turning left. In the second method (movement 2), the cyclists can use the pedestrian crossings, dismount and wait for the green walk signal at the crossing point together with the pedestrians. The third method (movement 3) is similar to approaches implemented in Australia and New Zealand (hook turn is called Perimeter style in British Columbia, Canada). In the third method, the cyclists move to the far right of the intersection and wait at the right side of the intersection, yield to pedestrians in a crosswalk and move forward when the traffic light turns green (ODOT, 2017).

Taiwan is a country, which ranks high in terms of the proportion of motorcycles to the other motorized vehicles. According to the crash statistics data, the majority of motorcycle accidents are related to the right of way accidents where motorcyclists violate the right of way of approaching automobiles. To reduce the negative impact of motorcycles, hook turns have been introduced in Taiwan as an engineering solution. As seen in Figure 9, the Hook Turn Area (HTA) is located in the middle of two parallel pedestrian crosswalks, and motorcyclists are required to perform a hook turn. The motorcyclists violating the hook turn rule will be fined. This measure is basically applied on roadways with two lanes or more (roadways wider than 8 m). This measure can reduce the risk of sideswipe and rear-end collisions which are common in left-turn crashes involving motorcycles and automobiles (Pai et al., 2013).

Similar to hook turns, two-stage left turn boxes have been implemented at several signalized intersections in Taiwan (Figure 10). The left turn boxes are installed after the pedestrian crossings. The rationale behind this approach is to provide a safe approach to make a left turn for motorcyclists at multi-lane signalized intersections (Le and Nurhidayati, 2016).

Impact on Traffic Safety

According to VicRoads investigations, a hook turn intersection has a lower rate of accidents and can operate better in terms of traffic safety compared to intersections with no hook turns (Marti et al., 2016). Hook turns can reduce traffic conflict points. Conflict points are the intersecting spots between the paths of different traffic movements. The conflict points can be classified into merging, diverging and crossing types. In this regard, hook turns can eliminate the conflict points between turning traffic, through traffic and tram movement, which results in the improvement of the intersection safety. The collision between trams and vehicles turning across the tramways is one of the common accident types at non-hook turn intersections, accommodating tram traffic (Figure 11). As tram

Figure 9 A schematic depiction of HTA for making a left turn (Pai et al., 2013).

Figure 10 An example of two-stage left turn box in Taiwan (YouTube, 2014).

Figure 11 A tram and car accident in Amsterdam (Flickr, 2020).

cars are much more massive than standard passenger cars, the severity of the collisions between trams and passenger cars is severe (Marti et al., 2016).

There are two main advantages of using hook turns and consequently removing the conflict points between through traffic and right-turn traffic. These advantages include the removal of right-turn head-on crashes and right turn-pedestrian crossing crashes (Currie and Smith, 2006; Currie and Reynolds, 2011; Naznin et al., 2018). The right turn head-on crashes are crashes that occur between right-turning traffic and the oncoming opposing traffic. This type of crash is dangerous due to the nature of the accident and

Figure 12 Comparison of conflict points at intersections with and without a hook turn (Bie and Liu, 2015).

the speed of involving vehicles. In addition, the investigations highlighted that conventional right turn traffic could increase the risk of collisions between pedestrians and right-turn traffic. In such situations, drivers of right-turning vehicles concentrate on finding the gap of sufficient size in the opposing traffic and leaving the intersection as soon as possible instead of focusing on pedestrians who may be crossing the streets in which right-turning vehicles are traveling. This study also suggests that the crashes occurred at hook turn intersections tend to be less severe than the ones that occurred at non-hook turn intersections.

Figure 12 shows a hypothetical four-leg intersection during the green time of the north-south signal phase. There are eight crossing conflict points between the right-turn traffic and the through movement. Also, four diverging conflict points resulted from the separation of left and right movements from the through traffic. Meanwhile, at intersections with hook turn implementation, there are only two diverging conflict points that resulted from the separation of right-turn traffic from left-turn traffic. Generally, the existence of a hook turn can remove the crossing conflict points at an intersection, which are considered as the main cause of traffic accidents (Bie and Liu, 2015).

A study was carried out analyzing the crash statistics data in metropolitan Melbourne between 2006 and 2008, and the conflict points associated with the normal right turns versus hook turns at tram intersections in metropolitan Melbourne. According to this investigation, the number of crashes at intersections with hook turn is lower than the corresponding number at the ones without hook turns. Vehicles at intersections with hook-turn treatment are less exposed to road safety hazards than those at intersections without the hook turn treatment (VicRoads, 2010). Also, Pai et al. (2013) suggested that based on official crash statistics in Taiwan, after implementing HTA, motorcyclists' death rate has been decreased noticeably. In this regard, in the first year of hook turn implementation, the number of deaths decreased from 719 to 593 and in the second year dropped to 529 deaths.

Traffic Management Improvement

Analysis of the turn volumes at a number of hook turn intersections within the Melbourne CBD between 1986 and 1999 reveals that the right-turn traffic volume had decreased in most cases. The capacity of the hook turn to discourage turning right, which can ease the left turn has been studied in a series of surveys conducted for urban and rural/tourist drivers. According to this survey, 39% of urban drivers and 38% of rural/tourist drivers stated that they had avoided right turn movement through hook turns.

To evaluate the potential impact of hook turns on the travel time of trams, a series of field surveys carried out during the morning peak period at a number of intersections in metropolitan Melbourne in 2010. In this survey, the traffic volume of right turning movement of hook turn intersections and non-hook turn intersections have been investigated. According to the outcome of this experiment, hook turn intersections can reduce the delay experienced by trams between 11 and 16 seconds per tram-intersection movement. This reduction in traffic delay is equal to saving three to five trams from being deployed to the public transport system compared to non-hook turn intersections. If the cost of each tram is considered as \$5 million, then the total saving cost would be between \$15 and \$25 million (O'Brien, 2000).

Limited studies have been conducted to analyze the traffic performance in terms of capacity and delay before and after implementing the hook turns. Meanwhile, there are some studies that investigated the impact of hook turns on intersections by using microscopic traffic simulation packages and providing before and after scenarios for hook turn implementation. O'Brien (2000) conducted traffic simulation studies to evaluate the performance of hook turns in metropolitan Melbourne. To analyze the performance of hook turns in Melbourne,

seven major intersections with hook turn were selected in those studies. For this purpose, SIDRA software was used. The analysis compares the performance of those intersections with hook turns against the performance of the same intersections without hook turns when the right-turn traffic use and occupy the tram line to make right turns. For this comparison, the degree of saturation has been used as a measurement for the intersection capacity. According to the results, the degree of saturation was much lower in four of seven hook turn intersections compared to non-hook turn intersections. For the other three intersections, removing the hook turns caused a slight improvement in the traffic operation. However, this study suggests that the overall traffic performance within the Melbourne CBD has been improved by implementing the hook turns. This study suggests that hook turns may improve traffic capacity and reduce traffic congestion by separating the right-turn traffic from through traffic and consequently enhancing the movement of through traffic. However, it must be mentioned that hook turns may account for the delay in left-turn traffic. Therefore, the performance of hook turns depends on the volume of turning vehicles. In addition, due to the unfamiliarity of drivers with the hook turn or other unknown reasons, some drivers avoid making a hook turn. This can increase the capacity of the hook turn intersections.

Hounsell and Yap (2013) studied the impact of hook turns on four-leg intersections using a microscopic traffic simulating package. In that study, two hypothetical four-leg intersections with and without a hook turn in London were modeled. For the model development, various traffic scenarios based on different traffic volumes, turning ratios, green splits, and signal timings were examined. According to the findings of this study, the hook turn can provide positive outcomes in terms of reducing the total intersection delay when the right-turn and left-turn traffic volumes are low since the hook turns result in less delay to left-turning vehicles, and fewer left-turning vehicles are required to queue up. Hounsell and Yap (2013) also suggested that the hook turns can be beneficial when the volume of through traffic is high as the hook turn approach can avoid blocking the through traffic at intersections. Also, the opposing traffic flow can take advantage of the hook turn as the obstruction of opposing through traffic caused by right turn traffic is eliminated. In general, when the overall traffic is high, the simulation results demonstrated better traffic performance when the hook turn is implemented to an intersection. This study suggests that outside of the above conditions, hook turn implementation may cause additional traffic delays compared to the conventional intersections without hook turns, mainly because of blocking the left-turn movement.

Bie and Liu (2015) studied the traffic impact of hook turn implementation at two similar intersections with a tram line using microscopic traffic simulation software packages. In this study, both intersections are equipped with Actuated Control Method (ACM) for signal controlling and adjustment. This feature can adjust the signal timing dynamically. This system actively monitors the traffic volumes at all approaches using sensors and loop detectors. ACM is beneficial to cope with the spillover of turning vehicles. ACM can assist intersections in taking the full advantage of the hook turn structure/performance. Using VISSIM microscopic traffic simulation software in this study, the traffic performance of hook turn and non-hook turn intersections were analyzed and compared. In this study, the average delay and vehicle capacity were used as the main performance indicators. The simulation results express that when average and low traffic volumes are observed at intersections, applying hook turns result in a larger average delay compared with the non-hook turn intersections. However, the simulation results for intersections with high total traffic volumes or the high right turn volume ratios show that the hook turn intersections experience lower average delays compared with non-hook turn intersections. This study suggests that the advantage of introducing hook turns is more visible when the ratio of right-turning vehicles is high. When the ratio of right-turning vehicles is low, the capacity of the hook turn and non-hook turn intersections are similar. In general, the hook turn approach improved the performance of right-turning and through vehicles in terms of the total vehicle capacity of the intersection.

Limitations and Disadvantages

Right-turn traffic volume is an important factor in the successful operation of hook turn intersections. The volume of right and left turns needs to be carefully counted/estimated as the right-turn traffic can block the left-turn approach, and this may lead to a long queue for the left-turning vehicles. Moreover, as Currie and Reynolds (2011) suggested in their study, lack of understanding and driver knowledge is a major constraint on the extensive implementation of hook turns in metropolitan Melbourne. Although hook turns are implemented in Melbourne for more than 60 years, around 6% of urban drivers struggled to understand and perform hook turns. It could be worsened when rural or tourist drivers who are not familiar with Melbourne CBD roads are confronted with hook turns. According to this study, 19% of non-commuters struggled to understand how the hook turns work.

According to Le and Nurhidayati (2016), the hook turn implementation can be a challenge because of the potential conflict between through traffic and left-turning vehicles. During the peak hours, the number of motorcyclists waiting to make left turn can overflow the left turn box and subsequently spill into other traffic lanes and the pedestrian crossings. This overflow can increase traffic congestion and reduce traffic safety at the pedestrian crossings of the intersections. As a result, it is clear that prior to the implementation of hook turn approach in new locations and environments, improving the knowledge and understanding of drivers with regard to hook turn rules and regulations as well as drivers' acceptance is essential.

Summary

In this study, the performance and impact of hook turns on intersections and tram movements have been investigated. Hook turns as an alternative way for right turn approach has first been introduced in metropolitan Melbourne. The primary purpose of introducing

hook turns was to keep tramways clear of the right-turning vehicles. Hook turns can have positive safety impacts on intersections as they can effectively reduce the number of conflict points at intersections. By applying the hook turns, the conflict between the right turn traffic and the trams as well as opposing through traffic, can be eliminated. The right-turn head-on crashes are server crashes that may occur at intersections where the right-turn movement is permitted. Overall, vehicles passing through intersections with a hook turn treatment are less prone to the traffic safety hazards compared to the vehicles that pass through the same intersection without a hook turn. In terms of the intersection performance, different studies and traffic simulation experiments have carried out to assess the performance of hook turns. In summary, hook turns may improve the capacity of the intersections. The role of hook turns is more highlighted when the right of way of tram and the reduction in their experienced delay time are targeted. With this regard, the through traffic can take advantage of hook turns as the right-turning vehicles can obstruct the opposing through traffic. However, the hook turns have some limitations. The ratio of right-turn traffic needs to be considered in hook turn implementation as they can obstruct the left-turn traffic and impose excess delays to this approach. Moreover, lack of understanding and driver knowledge can be a major obstacle to the proper implementation of this approach.

Finally, due to the lack of comparative research and before-after studies related to the hook turn implementation, it is recommended to conduct more studies to provide more accurate assessments of the hook turn approach.

Signal Coordination Definition

Adjacent traffic signals can be timed such that a group of vehicle (a platoon) would go thru the intersections without stopping. Traffic signal coordination (or traffic signal synchronization) is a process by which the beginning of green time at the subject intersection is determined such that the platoon of vehicles arriving from the upstream intersection would traverse without stopping. When traffic signal are well-coordinated, travelers would see green signal indications as they approach successive intersections. A proper signal coordination plan can result in safe and efficient intersection operation.

Signal Coordination Goals

There may be one or more of the following goals for signal coordination:

1. Optimize traffic signal operation;
2. Minimize delay, number of stops, travel time, etc.;
3. Maximize traffic throughput, speed, green utilization, etc.;
4. Reduce frequency or severity of crashes and improve traffic safety;
5. Allow pedestrian crossing at midblock crosswalk.

Efficiency of intersection operation can be high when vehicles are platooned and they are allowed to pass thru intersections with minimal delay. Vehicles in platoon maintain shorter headways and that increases the number of vehicles that go thru the intersection in a given time.

When a platoon travels a longer distance, it is more likely that the vehicles in platoon would disperse more and that would reduce the efficiency of traffic signal operation. Vehicles in platoon can stay pretty much intact miles or longer (Figs. 1 and 2).

Figure 1 Example of a dense platoon of vehicles.

Figure 2 Example of a partially dispersed platoon of vehicles.

When to Coordinate Traffic Signal

Signals that are located close to each other should be coordinated. What is considered “close”? It depends on travel time and/or the distance between the two adjacent intersections. The higher the travel speed the longer the distance between the two signals can be. Generally, if it is under 1 mile on streets/highways with higher speed limits (55 mph), it may be considered as “close”. The Manual on Uniform Traffic Control Devices ([MUTCD, 2003, 2009](#)) considers 0.5 miles as “close” and the Signal Timing Manual ([Urbanik et al., 2015](#)) and Traffic Signal Timing Manual ([Koonce et al., 2008](#)) considers miles as “close”. If traffic signals are too close to each other (e.g. about 1000 ft or less), they may be treated as “one” signal. In deciding to coordinate or not one should consider traffic volume, operating speed and travel time between intersections, elements causing platoon dispersion, and feasibility of keeping a dense platoon.

When traffic volume is low, signal coordination may not be very advantageous since the number of vehicles in queue would be low. When speed is high and travel time is short, platoon does not dissipates much. However, when speed is low and travel time is long, the vehicles in the platoon may disperse.

Signal coordination may be done along an arterial or on a network of intersections. The coordination may be on one direction of travel or on both directions. While signal coordination on one-way arterial is relatively straightforward, it gets complex on two-way coordination; and even more complex when a network of intersections are coordinated.

Signal Coordination Elements

Three important elements need to be determined:

1. Cycle length
2. Splits (green times)
3. Offsets

Cycle Length

In general, a common cycle length is used for all coordinated signal. The common cycle optimizes the operation on arterial (network) level and may not be the optimal cycle length at every intersection. Each intersection may have an optimal cycle length that is different than the common cycle length. In unusual cases and special conditions, the cycle length may vary at different intersections. The cycle length for unusual cases may be even multiple of the common cycle (1/3, 1/2, 2, 3 times). Using different cycle length on an arterial (network) makes the signal coordination more complicated, but that has been used ([Abu-Lebdeh and Benekohal, 1997a,b, 2000a,b](#)). The half common cycle (1/2 of common cycle) may be used when an intersection is far from the rest of the intersections and coordination is more important in one direction. The double cycle may be used at the key intersection when it is located in the middle of two groups of intersections.

To determine the common cycle length, a lower bound (minimum cycle length) and an upper bound (maximum cycle length) is decided. Often, the minimum cycle length is 50 s and the maximum is around 180 s. Then, the common cycle length is determined by finding the cycle length that optimizes the performance measure for the entire corridor (or network). The common cycle length is found by trying different cycle lengths within the specified range at small increments (like 10 s). The performance measure often used is delay. In some occasions, a combination of delay with another performance measure such as number of stops is used. Using the combination of two or more performance measure gets complicated because the performance measures use different variables and have different units.

Split and Green Time Allocation

Green time available during a cycle is divided among the phases. Split shows the portion of cycle that is allocated to a given phase. Split is composed of green, yellow change interval, and red clearance times. Most part of the split is the green time. The green time

should be long enough to process the vehicles that arrive in one cycle when the intersection is not oversaturated (under saturated). When intersection is oversaturated, the demand becomes larger than the capacity of the intersections. The green time should not be wasted. Green time is wasted when it is not utilized efficiently. Efficient green utilization is when vehicles go thru intersection at a steady departure rate. A reasonable range for the steady departure rate is 1.8–2.2 s per vehicle. The default saturation flow rate for signalized intersection in Highway Capacity Manual is 1900 passenger cars per hour per lane. This translates to a departure headway of 1.89 s.

To estimate the amount of green time needed to process “ N ” vehicle per cycle, one may use “2 + 2 rule”. The 2 + 2 rule implies that give 2 s of green to start with and for every vehicle give 2 s of green. It is mathematically may be expressed as: Estimated green time = $2 + 2(N)$.

This expression gives a good estimate for the lower bound of the green time. When start-up lost time is longer or there are vehicles that use longer headways (such as trucks) the estimated green time should be increased. When vehicles are departing at a headway less than 2 s, the estimated green time may be decreased. This estimate may be used to allocate the green time to the minor street. The major street may get the remaining green time.

A split time indicates the proportion of cycle length allocated to that phase. Split time = green time + yellow change interval + red clearance time. Summation of split times gives the cycle length.

Offsets

An offset is the time difference between the beginnings of green times (usually) for the phases to be coordinated. Offset is often expressed relative to adjacent signal. It can be referenced to any point in cycle or a reference point in time. Offset is often less than a cycle, but it can be greater than cycle if the reference point is not adjacent signal. Offset can be positive, zero, or negative.

A positive offset indicates that the downstream phase will start after the corresponding upstream phase. A zero offset indicate the corresponding phases start at the same time. A negative offset indicates that the coordinated phase at the downstream intersection will start earlier than the corresponding phase green at the upstream intersection. The negative offset is used to clear the vehicles are at the downstream intersection before the vehicles from the upstream intersection arrive.

Computing Offsets

The two important variables in offset determination are: speed and distance between the two intersections. An “ideal” offset is computed by dividing the distance by speed.

$$t_0 = L/S$$

where t_0 is the offset when there is no queued vehicles (ideal offset) (s), L is the distance from one stop bar to the next (ft), S is the average speed of vehicles on that section of the road (ft/s).

Often the posted speed limit is used for computing the offset. Other speed such as average operating speed or a given percentile speed may also be used. Using a speed higher than the speed limit yields a shorter offset and that may encourage speeding. On the other hand, using a lower speed yields a longer offset and that result in an inefficient operation because the arriving vehicles in platoon encounter a red light and are forced to stop.

Effects of Vehicle in Queue on Offset

Offset computation is straightforward when there is no vehicle in queue at the beginning of green at the downstream intersection. However, when there are vehicles in queue at the downstream intersection, the time to process the queued vehicles (Z_q) is subtracted from the offset

$$t_q = L/S - Z_q$$

where t_q is the offset when there are vehicles in queue at downstream intersection (s), Z_q is the time required to process the vehicles in queue at downstream intersection (s).

Z_q depends on no of vehicles in queue at the end of red phase (Q_r). These vehicles may come from minor streets or driveways between the intersections during red, or they may be left over vehicles from the previous cycle.

$$Z_q = Q_r(h) + l_r$$

where Q_r is the number of vehicles in queue at the end of red phase, h is saturation headway (s). l_r is the start-up lost time for the queued vehicles (s).

Fine-Tuning Offsets

Often the computed offsets are fine-tuned in the field to account for the “factors” that were not considered in computation of the offsets. For example, pedestrian crossing in midblock, bus stops, or vehicles entering/exiting from the minor streets or driveways can affect the travel speed and thus the offset. In addition to the factors not considered in computing offset, the offsets are affected by the errors and inaccuracies in the variables used in offset calculation.

$$t_{qf} = L/S - Z_q + t_1 - t_2 - t_3 + t_0$$

where t_{qf} is the fine-tuned offset when there are queued vehicles, t_1 Time (s) that takes for the first vehicle in platoon to reach the speed used in finding offset. If $t_1 = 0$, it indicates the lead vehicle instantaneously reached the speed and traveled zero distance, t_2 Time it takes for the leader of platoon to travel the distance over which it reached the speed used in finding the offset. If $t_1 = 0$, then $t_2 = 0$, t_3 Time (s) the green at downstream intersection starts a little earlier to prevent the platoon leader from slowing down due to seeing a red light ahead, t_0 Time added or subtracted to take care of factors that are not presented by other adjustments.

If we assume $t_1 - t_2 - t_3 = 0$, and $t_0 = 0$, then no adjustment is needed due to acceleration, traverse time, and deceleration.

Movement Numbering Scheme

Each vehicular and pedestrian movement are numbered, as shown in the numbering scheme. Left turns are numbered 1, 3, 5, and 7. Through movements are numbered as 2, 4, 6, and 8. The right turners are numbered as 12, 14, 16, and 18. Pedestrian movement, regardless of its direction of travel (e.g. from east to west or from west to east) are numbered 2P, 4P, 6P, and 8P. Often phase 2 and phase 6 are the major street through movements (Fig. 3).

Actuating Coordinated Phase

Normally, the coordinated phases do not have vehicle detectors since the other phases have detectors. However, the coordinated phase can be actuated during the last portion of its green time. The actuation allows to terminate the coordinated phase earlier when there is no demand on it (Fig. 4).

Figure 3 Movement and phase numbering scheme.

Figure 4 Actuated portion of coordinated phases.

In the sketch phases 2 and 6, which are coordinated phases will be allowed to gap out to terminate the phase earlier. This allows the minor street get green quickly. If “actuated time” is too large, it may cause the coordinated movements to gap out just prior to the arrival of the platoon. If “actuated time” is too small, it may have inconsequential result.

Transition Logic

Traffic signal operation pattern (cycle, splits, offsets, phase sequence) may change due to time of day schedule, emergency vehicles or train arrival interruption of normal operation, pedestrian signal activation that last longer than the vehicular green time, or other reasons. When the pattern is changed, operation goes thru a transition time and a logic to switch to the new pattern. The transition time often is over a few to several cycles. The transition logic takes operation from one pattern to another pattern. Excessive changes in pattern of operation is not good because of the transition time involved. Generally recommended to keep the pattern for at least 30 min (STM2). Changing patterns during congested conditions should be avoided.

Bandwidth

Bandwidth is the green time available for the vehicles in a platoon to go through a group of intersections without stopping. Bandwidth in a “good” one-way coordination plan can be equal to the shortest green time of the coordinated phases. Thus, green split at the intersection can affect the bandwidth (**Fig. 5**).

Band width (BW) efficiency (EB_{BW})

It is defined as ratio of bandwidth (BW) to cycle length (C). It is expressed as decimal or percent.

$$E_{BW} = (BW/C) \times 100$$

The BW efficiency often is not in 80's% or 90's% since green time is allocated to two or more phases. An efficient BW may be achieved at 40%–60% levels and it depends on the on shortest green time of the coordinated phase.

Figure 5 Offset and bandwidth at three consecutive intersections.

Capacity of bandwidth (C_{BW}) is defined as the number of vehicles that can travel within the bandwidth and go through all the coordinated intersections without stopping. Bandwidth capacity in units of vehicles/hour/lane can be expressed as

$$C_{BW} = (BW/h)(3600/C)$$

where h is saturation headway (s), C is cycle length (s), and BW is bandwidth (s). Bandwidth capacity cannot be greater than the capacity of the coordinated phase with the least green time. Queued vehicles at the downstream intersections can adversely affect the bandwidth capacity, if they are not processed before arrival of the platoon of vehicles.

Single Band Versus Multiband

A single bandwidth can always be maintained among the signal located on a one-way street. When several intersections are coordinated, more than one band (multiband) may be possible among a sub-group of the intersections (see Fig. 9).

One-Way and Two-Way Signal Coordination on Arterial

An efficient signal coordination is possible when the signals are along a one-way street. However, two-way coordination the bandwidth in one direction may be reduced to accommodate the coordination in the other direction. In some cases, this accommodation may not be possible. Multibandwidths may be used along a long arterial, but it gets more complicated to implement.

Signal coordination in two directions is more complicated than in one direction mainly because offsets separately computed for one direction often messes up the progression in the opposite direction.

The offset in one direction between intersection 1 and 2 (t_{12}) plus the offset in the other direction (t_{21}) is equal to cycle length (one or multiple cycle lengths).

$$t_{12} + t_{21} = nC$$

This shows that the offset are interdependent (Fig. 6).

Decisions Affecting Coordination

- Selecting a different bandwidth in main direction
- Changing speed
- Changing cycle length
- Chang green splits
- Changing phase plan to change green time
- Restricting minor street access to right in right out
- Removing the traffic signal (eliminate the access)

Figure 6 Offset in one direction and its relation to offset in other direction.

Figure 7 Simultaneous signal coordination scheme.

Signal Progression Schemes

The most common type of signal progression is what was discussed previously. Some call this “simple” progression when there are no queues at intersections. Simple progression is also called “forward” progression. If progression is revised during the day to provide a different priority some call it “flexible” progression. When upstream intersections start earlier than subject intersection (negative offset) it is referred as “reverse” progression (Roess et al., 2011).

Special Signal Progression Schemes

Simultaneous System

That is when the coordinated phases at different intersections start at the same time. This can be used for intersections that are very close to each other, or the offset is equal to the cycle length (Fig. 7).

Alternate System

The progression is such that every other intersection starts simultaneously (Fig. 8).

X-ple Alternating

Double (triple, quadruple) alternating—if there are two (three, four) intersections are considered as a group and you have alternating system between the groups (Fig. 9).

Figure 8 Alternating signal coordination scheme.

Figure 9 Double alternating signal coordination scheme.

Force Off

Refers to a time during cycle that the uncoordinated phases must end (even if there is demand for longer green) to ensure that coordinated phase would start as planned. There are two types of force offs: Floating type or fixed type. The type indicates how unused actuated green time of uncoordinated movement is allocated to the subsequent phases. In floating force off, the unused green is given to the coordinated phase (force off point of the uncoordinated phase to coordinated phase is floating (not fixed)). In fixed force off, the unused green is given to the following phase (force off point of the uncoordinated phase to coordinated phase is fixed).

Offset Reference Point

Defines the point in time, relative to master clock, the cycle begins. It can be variety of points in cycle. Modern controller allows options such as: Strat of green for the first coordinated phase (used in TS2); Strat of green for both coordinated phases (used in TS 1); Strat of FDW for the first coordinated phase; Strat of yellow for the first coordinated phase (used in 170).

Signal Coordination in Oversaturated Conditions

Signal Coordination in oversaturated conditions becomes more complex due to queue spill back and lane blockage preventing enough demand to reach downstream (starvation). In oversaturated conditions, queue management is more appropriate measure of effectiveness than delay (Abu-Lebdeh and Benekohal, 1997a,b, 2000a,b, 2007). Abu-Lebdeh and Benekohal developed a dynamic traffic signal control algorithm for oversaturated arterials to dynamically manage queue formation and dissipation. For a one-way arterial, their method provided dynamic time-dependent traffic control. Offsets and green times were dynamically changed as a function of demand and queue lengths. They found similar results for a two-way arterial (Abu-Lebdeh and Benekohal, 1997a, b, 2000a,b).

For real-time dynamic signal coordination, Intelligent search and optimization technique need to be used to find the optimal solutions due to the large search space of the solutions. Girianna and Benekohal (2004) and Hajbabaie and Benekohal (2013) used genetic algorithm (GA) and Medina et al. (2013) used reinforcement learning to find optimal signal coordination plan for oversaturated networks. For oversaturated conditions, the signal timing optimization may be done over multiple cycles (Abu-Lebdeh et al., 2007).

Introduction

Emergency vehicle priority or emergency vehicle preemption (EVP) is a form of preferential treatment used to give emergency vehicles (EV) a priority green light at an intersection. EVP interrupts the normal operation of traffic signals for EV to cross an intersection and then returns to normal operation after the EV passes the intersection. Vehicles that are designated and authorized to respond to an emergency in a life-threatening situation such as police vehicles, ambulance, and firefighting vehicles are referred to as EVs. EVP aims to reduce the EV's travel time and enables it to respond to an emergency call for an incident with a minimum delay.

Although signalized vehicle preemption is a relatively recent development resulting from advancements in Intelligent Transportation Systems (ITS), the concept of prioritizing emergency vehicle movement is not. Emergency vehicles were and are still prioritized on streets using sirens and strobe lights. However, intersections remained to hinder it from moving uninterrupted. In the 1960s, hardware technology to detect vehicles using vehicle-based emitters and signal-based detectors emerged which provoked the concept of EVP at signals.

Though EVP interrupts and might increase the delay for general traffic, it has several benefits such as:

- Reduce the probability for an EV to receive a red signal, and as such, reduce travel time.
- Reduce the likelihood of crashes at intersections by clearing the traffic queues from the path of the EV. Thereby, it assists in safely and effectively responding and attending to emergency incidents
- Increase the potential for saving lives by providing faster access to incidents
- Decrease the potential disruption to the road network by clearing the incident faster
- It helps to support the emergency response personnel to meet response targets
- Assists EVs to manage increasing demands
- EVP can also be adapted for other modes of transport, such as buses and heavy vehicles
- It gives a policy-based approach for giving priority to road users
- It provides a safe work environment for front-line officers.

This article presents a brief review of EVP systems deployed in practice as well as the state-of-the-art research on EVP operation.

EVP State of the Practice

Automatic vehicle location (AVL) systems such as global positioning systems (GPS) are used to determine the location of an EV and calculate estimated times of arrival at intersections. Further, a message is sent to the traffic controller that an emergency vehicle is approaching using vehicle to roadside communication (VRC). After receiving the preemption call, which may include the expected time of arrival at the intersection and signal phase requested by EV, traffic controller generally follows the steps shown in Fig. 1. First, after receiving the preemption call, the current status of the phase requested by EV is checked. If the status of the requested phase is red without or with pedestrian movements active in conflicting phase, then the requested phase is tuned green only after serving yellow, and all red or minimum pedestrian clearance time, yellow and all red to conflicting phase. If the status of phase requested by EV is green, then the green time for the phase is extended to serve the EV request. Once the request is served, the transition algorithm is applied to exit out of preemption.

Figure 1 General framework for preemption logic. EV, emergency vehicle

It is essential to understand that EVP is different from transit signal priority (TSP), which is a treatment used to give priority to transit vehicles such as buses, trams, etc., at a signalized intersection. EVs have an absolute (or highest) priority whereas TSP offers priority to transit vehicles only when it is possible to do so without disrupting normal signal operations. For example, TSP operation is not allowed to skip or override signal phases to serve the phase requested by a transit vehicle. In contrast, EVP operation can do so to offer a priority to EV.

Communication Technologies for EVP

The major technologies currently used for communicating with traffic controller include light or infrared-based systems, sound-based systems, and radio-based systems (Paniati and Amoni, 2006). Each of these systems has its advantages and disadvantages as shown in Table 1.

Table 1 Communication technologies used for EVP operation

Technology	Dedicated vehicle emitter required	Susceptible to electronic noise interference	Clear line of sight required	Affected by weather	Preemption possible on other approaches
Light or infrared system	Yes	No	Yes	Yes	No
Sound-based system	No	No	No	No	Yes
Radio-based system	Yes	Yes	No	No	Yes

EVP, emergency vehicle priority or emergency vehicle preemption.

EVP Systems of the Real World

Examples of EVP systems deployed around the globe include EVP practice in Maricopa Association of Governments (MAG) region (MAG, 2018), the SAFER system deployed in China (Tokuda & Ohmori, 2011), EVP system in Victoria, Australia (Intelligent Transport Systems Group, 2005), STREAMS EVP by Transmax (2018), Tongji Emergency Vehicle Signal Preemption System (TJ-EVSP) (Wang et al., 2013), Plano Texas EVP System and Fairfax County Virginia EVP System (Paniati and Amoni, 2006). Other real-world EVP systems are OPTICOM emergency response by Global Traffic Technologies LLC, (2020), STROBECOM II system by TOMAR Electronics Inc. (2020). All these systems use infrared signals for communication between EV and signal control infrastructure.

Abovementioned preemption systems operate on an intersection-by-intersection basis. Sensors detect an EV at each controller and each controller switches to a predefined preemptive phase. This result in preemption of each intersection only after the EV reaches it which may cause the EV to wait at an intersection for vehicles to clear. This can also confuse drivers of other vehicles about whether to pull over or proceed in the presence of an EV at a preempted green. Local detection of an EV is further complicated by peak hour traffic or after-event traffic when the corridor is congested. In such conditions, pre-emption can create increased delays at local intersections due to lack of clearance at downstream intersections.

Very few route-based dynamic preemption systems have been found in the practice. The only route-based signal clearance research found from the literature was the Fast Emergency Vehicle Pre-emption System (FAST) developed by a group of Japanese researchers (Miyawaki et al., 1999; Shibuya et al., 2000). When an incident occurs, FAST is activated in support of the EV's operation. The traffic control center calculates the recommended route by which the EV can reach the scene in the shortest time; it uses the infrared beacon's position through which the vehicle is expected to pass and transmits the route information to the beacon. Then it conducts priority control, giving maximum signal green time and adjusting the offset at each intersection on the recommended route to make it easy for the vehicle to reach the scene. When it passes through the infrared beacon, the EV is informed of the recommended route and is given details about the situation at the scene in response to transmission of the vehicle identification (ID) information. The EV heads toward the scene along the recommended route. The infrared beacon notifies the intersection downstream of the direction taken by the EV and of the EV's approach, and it initiates another priority control extending green time or shortening red time to allow the EV to pass with a green light. The information board installed near the intersection warns civilian vehicles of the approaching emergency vehicle. The traffic control center uses advanced mobile information systems (AMIS) to provide traffic information about the surroundings and the occurrence of incidents to in-vehicle units mounted on civilian vehicles through the infrared beacons. As of the end of 2013, 15 prefectures had adopted FAST (Intelligent Transport Systems, 2014).

Transition Out of EVP

As presented in Fig. 1, after preempting a signal for serving a priority request from EV, some recovery measures/ transition strategies are necessary to transition from a preemption control plan back to the coordinated operation of the normal timing plan. If a traffic signal is operating in isolated or uncoordinated mode (e.g., fully actuated or free), decisions on how to exit from a preemption control plan can be made without considering the traffic progression between adjacent signals. To identify how the signal controller will exit or recover from a preemption control plan requires specifying a return interval or sequence of intervals that must be served. The sequence that is specified should be based on the conditions and constraints specific to each intersection.

However, to maintain coordination with adjacent traffic signals, exit transition strategies provide the capability to return the controller to a point in the signal timing plan where it would have been if it had not been preempted. Such a strategy should automatically perform the necessary adjustments to reach the desired reference or coordination point in the normal signal-timing plan. The adjustments are generally accomplished by holding in the desired return phase, or reducing or expanding the length of the signal timing plan until the desired coordination or offset point is reached.

Table 2 summarizes some of the widely used transition strategies in practice. Column one presents the name of the strategy, column two provides a brief introduction of the strategy, column three lists the signal controllers that support the particular transition strategy, and finally, the last column identifies the studies that evaluate the specific strategy. Few of the researchers (Obenberger & Collura, 2007; Yun et al., 2008) also performed a comparative evaluation of the transition strategies described in Table 2. These studies suggest that several traffic characteristics, conditions, and factors significantly influence the potential impacts of different exit transition strategies on traffic flow. Some of these factors are summarized below:

- Frequency and direction of travel for the vehicles requesting preemption
- Roadway capacity to accommodate turning movements to avoid any further disruption of traffic on all approaches to the intersection
- Travel demand and available roadway capacity (e.g., volume to capacity ratio)
- Presence and frequency of pedestrian phases or actuated calls
- Green time available in cycle length to be reallocated to accomplish the desired exit transition strategy
- Cycle length, number of phases, and intervals to serve in the signal plan; and
- Intersection spacing and quality of progression of traffic between successive traffic signals

Table 2 State of practice transition strategies to exit from preemption

<i>Transition strategy</i>	<i>Description</i>	<i>Controllers</i>	<i>References</i>
Dwell/ Hold	Corrects a misaligned coordinated phase (also known as the sync phase) by holding the coordinated phase green (i.e., dwelling) until it is aligned with the schedule in the new plan or is in sync	170E, 2070 ATC, Eagle EPAC300, Econolite ASC2S, Siemens NextPhase, Naztec Model 980	Shelby et al. (2006); Obenberger and Collura (2007); Yun et al. (2008)
Max Dwell	It is similar to Dwell logic, but the extra time spent dwelling in the sync phase is constrained each cycle—typically 20% of the cycle length. Thus, it may take multiple cycles to complete the offset correction.	Eagle EPAC300, Econolite ASC2S, Siemens NextPhase, Naztec Model 980	Shelby et al. (2006)
Long way/Add	Corrects the offset by lengthening the cycle, typically increasing all phase durations proportionally to their splits. The maximum amount of additional time added to each transition cycle is generally constrained to a specified percentage of the cycle length.	2070 ATC, Eagle EPAC300, Econolite ASC2S, Siemens NextPhase, Naztec Model 980	Shelby et al. (2006); Obenberger and Collura (2007); Yun et al. (2008)
Subtract	Corrects the offset by shortening phases (typically all phases), subject to minimum green time, pedestrian intervals, and an allowed decrease in the cycle length	Eagle EPAC300, Econolite ASC2S, Siemens NextPhase, Naztec Model 980	Shelby et al. (2006)
Minimax/ smoothed/ Shortest/best way	Implements either Add or Subtract transition, choosing whichever method is determined to get into sync earlier	170E, 2070 ATC, Eagle EPAC300, Econolite ASC2S, Siemens NextPhase, Naztec Model 980	Shelby et al. (2006); Obenberger and Collura (2007); Yun et al. (2008)
